equipment is still being unpacked and arranged. Here again we are indebted to the generosity of the Governing Body of the Indian Research Fund Association who have placed at our disposal a sum of Rs. 73,000 to which Your Excellency's Government has added Rs. 6,000 a year for three years. With the aid of these bequests I have undertaken to run the unit with a modified staff for three years without further cost to either body.

We are in need of a fully trained medical biochemist, and we have hopes of getting the services of such a one during this year. Meanwhile the work is being carried on by Mr. Malandkar, who was trained in biochemistry at the Bangalore Institute of Science.

A commencement has been made in the study of the biochemistry of sprue, the different aspects of which disease are also engaging the attention of Dr. Fairley, myself and others in the Laboratory. The particular work which the biochemical unit will be called upon to carry out is the estimation of chemical changes in the excreta and the blood, and the functional efficiency of the liver, pancreas and intestines in this mysterious disease. It is hoped by such team work that important results may be obtained throwing light on the causation and prevention of sprue.

(X) *Research Work.*—In addition to the work already referred to, I must briefly speak of the research work which is being carried on by members of the staff over and above their routine duties.

Dr. N. H. Fairley, a whole time research officer, has continued his observations on Bilharzia worm disease, guinea-worm infection and on the serological aspect of certain tropical diseases, the latter being a line of work in which he is a pioneer. He is also associated with others in the investigation of sprue.

Dr. Naidu, also a whole time research worker, who has been appointed by the Indian Research Fund Association, has carried out with Assistant Surgeon Khan Bahadur Avari a large amount of work in connection with the plague prophylactic and the means of improving its immunizing power and of reducing the local reaction at the site of injection. These researches are likely to yield important practical results.

Dr. Goré is still engaged in unravelling the complicated problem of the intestinal bacteria.

Captain Malone has been engaged on another aspect of the plague problem with the object of measuring the degree of immunity produced in animals and man by the inoculation of Haffkine's plague prophylactic. This promises to provide a method which has long been required.

Assistant Surgeon La Frenais, with Dr. Avari, is continuing his researches on rabies.

Assistant Surgeon Chitré and myself have been engaged on the intestinal aspect of the sprue problem for over a year, and we have accumulated a large amount of information which is shortly to be published.

That summarises very briefly the principal activities of this Laboratory during the past year, and I can with some confidence assure Your Excellency that the high standard and well known reputation of this Laboratory is not only being maintained, but I believe improved, whilst the new units staffed by keen and able men will enable us to push forward the boundaries of knowledge to the improvement of our control over tropical diseases and of methods for their prevention and cure.

What of the future?—There is no need for me to emphasise the importance of research to an audience of medical men. It is to medicine what the intelligence branch is to the army, being at the same time the "eyes" of observation and the advance guard of progress.

Research which stops at the laboratory is of no practical use, and our aim here is to bring the results of research to the notice of the combatant ranks of the

medical army. That is the object of our meeting here to-day.

It is necessary that we should bring our results down to practical problems, and particularly that the results of research should be made applicable to the problems of public health.

This was the theme of my presidential address at the recent Indian Science Congress, and I emphasise it again.

A mobile unit.—An organisation with this end in view is badly needed in Parel, and I suggest the establishment of a mobile laboratory which should be prepared to proceed at once on the outbreak of an epidemic, just as a fire engine stands ready to dash to the site of a fire. It would be a simple matter to arrange this, and all it would require would be a suitably trained medical man to take charge of this unit.

When the nature of the epidemic has been determined, its mode of spread will, in many cases, be obvious, or, if not, this also can be investigated, and the doctor in charge of the mobile unit will be in a position to co-operate with the public health authorities in limiting it or stamping it out. Such a link or liason is badly needed between research laboratories and public health authorities. A unit of this sort has already been established in Madras where it has yielded valuable results.

Tropical School.—Your Excellency, and you, ladies and gentlemen, will be aware that an elaborate scheme for the establishment of a School of Tropical Medicine at Parel was drawn up by my distinguished predecessor, Colonel W. G. Liston. Through the generosity of Sir Dorab Tata it seemed likely that the necessary sum of money would be raised. Just as the scheme approached fruition the Inchcape axe fell and the scheme had unfortunately to be abandoned. I hope, however, that it is merely postponed, and that when financial conditions are more favourable, one or more of the merchant princes of Bombay—a city already renowned for its public benefactors—will again come forward to provide facilities for higher medical education and thus remove from Bombay the opprobrium under which it lies in this matter. At present all our Bombay graduates have to go to Calcutta for their higher medical education, and this must be a reflection of a painful nature to the "first city in India."

In conclusion, I wish, for myself and my staff, to thank Your Excellency, and you, ladies and gentlemen, most heartily for your presence here to-day. You, Sir, in particular, because you are known to have the cause of medical advancement very much at heart, as your actions in many directions have already proved. We hope by eliciting your distinguished interest and by obtaining the support which your exalted position ensures, that the work of this Laboratory may be still further extended for the relief of suffering humanity.

Abstract from the "Times of India," dated 23rd February, 1925.

PAREL LABORATORY.

His Excellency, who made a short speech, said:—"On my own behalf and on behalf of the other guests who are present here this evening, I thank you for the welcome that you have been good enough to accord to us. I shall desire that the thanks are all on our side, for it is a real pleasure to us to have had an opportunity of visiting this Laboratory. I am quite sure you, gentlemen, expect me this evening to make an eloquent speech. I should be rash indeed if I merely attempted to deal with any technical subject before an audience, composed as it is, of men distinguished in medical research. I am expected to speak on a subject on which I know nothing at all, but I am a very frequent visitor to this Laboratory, and every visit that I pay here is a proof of the interest I am taking in this Laboratory. I wonder what Hippocrates would say

if he came back to the world again and visited this institution! It is an undoubted fact that as year passes year, as decade passes decade, medical science is making a progress, perhaps unparalleled in the progress of any other science, resulting in immense benefit to the suffering humanity and in the prevention of disease; and you, gentlemen, who have visited this Laboratory know what splendid work has been done by Lieutenant-Colonel Mackie and his staff."

After referring to the financial stringency from which the Government was suffering at the present time, he hoped that it would not be far distant when they would realise the scheme that was formulated before,—that there should be a School of Tropical Medicine in Parel. Surely if it was wanted anywhere in the world, His Excellency emphasised, the school was wanted in this Eastern country where they suffered so much. He hoped that those people who had been generous before would come forward to ease the financial position and help an object that was going to benefit not only Bombay but also the whole of the East. His Excellency was not, of course, in a position to make any definite promises, but assured them that if he could do anything that was possible in his power, he would certainly do it.

His Excellency, continuing, expressed his agreement with Colonel Mackie that it was a fact that the snake venom work might be regarded in part as popularising the Laboratory, in that it provided a *tamasha* which was witnessed by many distinguished persons. When one realised the enormous amount of work that was put through in the Laboratory every day by the anti-rabic unit, which was started only two years ago, and by the anti-plague department and the other activities of the institute, His Excellency thought that they in Bombay ought to be proud that they had in their midst such an institution, which was not only benefiting their city and Presidency, but was of immense value to the Eastern world. He also felt that the Laboratory had undoubtedly earned a very great reputation and was sure that it would continue to increase in future as it had done in the past. His Excellency offered his sincere thanks to Colonel Mackie and staff.

The Influence of Climate and Malaria on Yaws.

By G. C. RAMSAY, O.B.E., M.D. (Edin.), D.T.M. & H. (Eng.).

Jl. of Trop. Med. and Hygiene, Feb. 16, 1925, p. 85.

ACCORDING to Manson-Bahr in "Manson's Tropical Diseases," "Yaws is practically confined to the tropics and sub-tropics and even there, is absent at high altitudes, but owing to its great similarity to syphilis and the extent to which these two diseases overlap, it would appear to be impossible to define its exact limits."

Ramsay's experience in the Cachar district of Assam is that yaws is more prevalent among the hill tribes than it is among the inhabitants on the plains.

The district of Cachar is a low-lying plain broken up by isolated hillocks and surrounded by ranges of hills varying from 2,000 to 6,000 feet in height.

The lesions of yaws as seen on the plains and foothills during the warm, steamy weather are typically text-book in the primary and secondary stages.

The extra-genital mother yaw, the minute yellow-pointed papular eruption, the furfuraceous desquamation, the warty ring-worm or circinate yaws and the foot lesions (crab yaws) are as typical in Cachar as in other yaw-infected countries.

The effect of climate on these lesions is remarkable; during the cold season on the plains it is a very rare occurrence to see frambœsial patients presenting typical yellow-crusts excrescences, but condylomatous-like lesions in the warm, moist regions of the axilla and between the nates, chronic dermatitis of the hands, desquamating and worm-eaten-like lesions of the soles of

the feet and occasionally painful joints all liable to be mistaken as syphilitic are what is usually seen.

As soon as the weather becomes warmer the characteristic yellow-crusts yaws may reappear with, on the advent of the warm, rainy season, the painful plantar lesions.

The effect of climate giving the lesions of frambœsia a syphilitic appearance is doubtless one of the principal reasons for diagnostic errors in colder latitudes.

Heat and moisture, but principally the former, appear to be the main factors in producing the characteristic lesions of frambœsia, for the cooler the climate the more do yaws and syphilis resemble each other.

In an experience of over 1,000 cases, tertiary lesions, with the exception of chronic dermatitis of the hands and desquamation, exfoliation and pitted worm-eaten-like appearances of the soles of the feet, are comparatively uncommon.

Superadded infection of ulcers with Vincent's bacilli and Schaudinn's spirochaetes converting the characteristics of the frambœsial ulcer into those of tropical sloughing phagedæna with occasional serious sequelæ is by no means rare.

Arthritis is seen in about three per cent. of the tertiary cases, the interphalangeal joints of the fingers being most frequently involved, but bone lesions (periostitis) have only been seen in six cases and on two occasions juxta-articular nodules were seen in patients with a history, but no other signs of yaws.

It is a very noticeable fact that in Cachar the tertiary lesions of frambœsia predominate amongst the residents on the cooler slopes of the surrounding hills and not on the warmer malarious plains.

Climate *per se* fails to explain this anomaly, for severe tertiary lesions are, according to Manson-Bahr and Spittel, extremely prevalent in the much warmer climates of Fiji and Ceylon.

When investigating the reasons for the comparative mildness of tertiary syphilis and the absence of parasymphilitic affections in this district, it appeared to me that repeated malarial infection might be the possible explanation, for coolies imported from a non-malarious district usually appear to contract a much more severe type of syphilis than those born and brought up locally.

Powell mentions cases of yaws where frambœsial eruptions subsided after contracting severe remittent fever, and again remarks that yaws is most prevalent in gardens where the incidence of malaria is least.

Powell mentions cases of yaws where frambœsial malaria, but believed that fever due to other causes has also a beneficial effect, and in his conclusions on the effect of pyrexia, writes: "The fever to produce satisfactory results should be of some days' duration."

From Powell's observations, from his own investigations from the fact that Fiji is non-malarious, Ceylon very slightly so, from the fact that tertiary yaws in Cachar predominates on the cooler and less malarious hills, Dr. Ramsay concludes that the prevalence and severity of tertiary frambœsial lesions depends upon the absence, incidence and degree of malarial infection in a yaws-infected region.

Encephalitis Lethargica.

By ALEX GARDNER ROBB, M.B., B.Ch., D.P.H.
(R.C.P.S.I.),

Medical Press and Circular, March 4, 1925, p. 173.

This paper deals with an epidemic which occurred suddenly and extensively in Belfast last spring and early summer. The outbreak began in March; few cases at first, a large increase in mid-April, and continued till the end of June, when the epidemic ceased even more suddenly than it began. Only one case occurred after the end of June. This seasonal outbreak coincides exactly with the one in 1920, which was the only other extensive epidemic in Belfast.

The total number of cases admitted during this recent outbreak was 183, and nine-tenths of these occurred

within the period of mid-April to mid-June. In this epidemic, however, the disease was diagnosed early and patients were frequently in hospital during the stage of excitement and insomnia. Stress was laid on the importance of mental excitement, insomnia and talkativeness and early symptoms.

In this epidemic the prominent symptoms at the outset were:—(1) Fleeting neuralgic pains; (2) nocturnal insomnia, often complete and lasting for several nights; (3) mental excitement and exaltation, great restlessness and talkativeness. A little later came (4) diplopia and other eye symptoms; (5) muscular twitchings; (6) delirium of varying degree; and later still (7) lethargy.

In many of the cases one or more of these signs were absent. In some cases the first symptom was acute pain in the axilla or in perineum.

(1) Neuralgic pains occurred in the large majority, commonly in scalp, over ears, neck, often to shoulders and arm, forearm, thumb, iliac crests, frequently later bilaterally; pain in the foot was usually later. Pain more marked when the part was touched lightly, often disappearing with firm grip.

(2) Nocturnal insomnia: an early sign in the large majority.

(3) Mental excitement, restlessness and talkativeness; very common at the onset. Whistling was one of the accompanying signs in some cases.

(4) Diplopia was present in 73 per cent. of cases, generally occurred on the second or third day.

Squint, ptosis, nystagmus and partial loss of accommodation were frequent.

(5) Muscular twitchings occurred in some degree in 70 per cent. of cases; sometimes mild twitchings of the lips, some more severe and persistent, not of such an "abandoned" nature as in chorea. Myoclonic jerkings of abdominal muscles were common, often accompanied by much pain.

(6) Delirium occurred in 52 per cent. of cases, varied from low mutterings at night to severe maniacal states, usually only lasted for one or two days; they were not subject to night terrors. Hallucinations in several cases.

(7) Lethargy occurred at some stage in 72 per cent.; generally appeared second or third week.

Herpes occurred in 6 per cent. of cases, usually on the lips and nostrils.

Respiratory disturbances; polypnoea frequently noted both in early and late stages (60-80 or even 100 per minute).

Complaint of shortness of breath was frequent even in cases already several weeks ill. Rapid breathing sometimes remained as a sequela. Polyuria was common.

Cerebro-spinal fluid was examined in many of the cases, little variation from normal except an increased sugar content. Many estimations of sugar were made for him by Dr. J. H. Smith. It was found above normal in every case, no matter what the duration of the illness. This increase is a valuable diagnostic sign in differentiating from various forms of meningitis. If no increase then encephalitis is not present.

Same house frequently provided several cases. Some such cases separated by intervals of four weeks. No member of the hospital staff contracted the disease.

Paralysis of facial nerve was very uncommon.

Prognosis.—Previous epidemics have provided rather misleading statistics. Death-rate in the last epidemic was 11.4 per cent.

Dr. Robb expressed himself as very sceptical regarding the recovery rate, usually quoted 20 per cent. He estimated about 5 per cent. as being nearer the mark.

Riddoch has reported the results in 83 cases which recovered from the acute attack in the London Hospital. Examined at long intervals after discharge, "residua in almost all" (Hall), and said his own experience almost coincided with this. He was unconvinced that hexamine had any value. Sodii salicylate was of very little use for the pains. Paraldehyde of great value in free and repeated doses.

He was not impressed by results of fixation abscess. Diphtheria antitoxin improved one case, but in half a dozen subsequent cases had no effect whatsoever.

He was not impressed by intravenous injection of patient's own C.S. fluid, and was not satisfied that repeated lumbar drainage was of benefit.

Mosquitoes and Coconut Palms.

By W. E. HAWORTH, M.B., C.M., B.Sc.,

Transactions of the Royal Society of Tropical Medicine and Hygiene, October 1924, Vol. XVIII, No. 4, pp. 162-198.

THIS is an account of the running to earth—or rather tracking to the tree tops—of so many "Peter Pan" imps in the form of innumerable mosquitoes which otherwise had eluded all the vigilance of the author and his staff, who were engaged in making Tanga in Tanganyika Territory a pleasant abiding place. The meticulous care with which the axils of the coconut palm fronds were ascertained to be the site of breeding places for the insects is recounted, and among the more interesting detailed observations are the facts that the water in these breeding places persists for a very long time during the hot, dry season, and that the species found include *Culex fatigans* and *Anopheles costalis*: the latter was present in 58 out of 8,887 specimens. Dr. Haworth recommends the clearing out of palms from township areas as the only possible way of tackling the problem.

Reviews.

AN INTRODUCTION TO PRACTICAL BACTERIOLOGY.—By T. J. Mackie, M.D. (Glas.), D.P.H. (Oxford), and J. E. McCartney, M.D., D.Sc. (Edin.). Edinburgh: E. & S. Livingstone, 1925. Pp. 304. Price, Rs. 6-6 net or 8s. 6d. Obtainable from Butterworth & Co. (India), Ltd., Post Box 251, Calcutta.

WHEN the reviewer was a student he consulted his professor of pathology as to which book on bacteriology he should buy; the reply that he received was, "Don't waste your money on a book; all books on bacteriology are out of date before they are printed." In those days the few notes that one took in the pathology lectures and practical classes sufficed both for examinations and for all the practical laboratory work that the student was likely to do. Nowadays the case is somewhat different; the bacteriological kaleidoscope does not change quite so rapidly, but the whole field of bacteriology is so much more vast that, unless the student is prepared to spend months digging into the large textbooks on the subject, he must be provided with a handbook such as the one under review.

This book is written primarily for the use of students and is meant to be an introduction and a guide to practical bacteriological laboratory work; it is not meant to be an epitome of medical bacteriology. The authors have attempted to emphasise the more important methods used in routine bacteriological diagnosis, recommending those that they have found most useful in their own experience.

The authors have produced a book which should prove very useful alike to the fifth-year student, the post-graduate student and the practitioner. They have dealt with the whole range of practical bacteriology thoroughly, but at the same time concisely. They have not confined themselves strictly to bacteriology but have strayed into the subject of protozoology and have dealt with the laboratory diagnosis of such diseases as

malaria, amœbic dysentery and trypanosomiasis. This diversion is particularly welcome to the student in the tropics whose practical laboratory work is likely to consist of far more protozoology than bacteriology.

The book is well written, clearly printed, and of a very convenient size.

AN INTRODUCTION TO THE HISTOLOGY OF TUMOURS.—By H. A. Halg, M.B., B.S., D.P.H. London: Henry Kimpton, 1924. Pp. 128, with 28 text figures and 10 plates. Price, 7s. 6d. net.

THIS is an elementary work on the histology of tumours, designed apparently chiefly for students. With it is combined a brief description of some technical methods. In view of the fact that this ground is adequately presented to students in the well known textbooks of pathology, this work will only be of subsidiary assistance to them.

A slip has occurred on p. 55 where *Schistosoma hematobium* is referred to as a nematode worm.

G. S.

LOCAL ANÆSTHESIA SIMPLIFIED.—By J. J. Posner, D.D.S. St. Louis: The C. V. Mosby Co., 1924. Pp. 114, with 55 illustrations. Price, \$3.50.

THE title of this book is well chosen inasmuch as it is written in very simple language, the technique is simple and the apparatus is simple. The photographs and illustrations are very clear and instructive and are easily the best we have seen dealing with this subject.

In the chapter on the instrumentarium we should like to have seen the use of curved needles mentioned, as we have met with many cases where it would be almost impossible to inject into the muco-buccal fold in the region of the upper wisdoms with a straight needle on account of a tight cheek or the inability to open the mouth sufficiently wide.

We also prefer to sterilize the syringe immediately before and after use by boiling and do not think it wise to put trust in such apparatus as a glass butter jar, as the author suggests, for safe custody after sterilizing after use until the syringe is required again.

Sterilized ampoules containing an old solution may be all right, but again the risk is present and not worth the while. It is much safer to make a fresh solution daily, using newly prepared twice-sterilized water, Ringer's solution tablets and Novocaine E and F tablets.

We should like to have seen more about the use of suprarenin, as there is no doubt that many of the toxic symptoms following an injection may be traced to this drug.

No mention is made of the importance of the solution being isotonic, a variation from which is the most common cause of after-pain and we think a chapter on the dangers, contra-indications and untoward effects could have been introduced with advantage.

The book is well printed on excellent paper and very free from errors, and should be of great help to the dental surgeon wishing to improve his technique, but we can scarcely recommend it to an inexperienced student.

NUTRITION OF MOTHER AND CHILD.—By C. Ulysses Moore, M.D., M.Sc. Philadelphia and London: J. B. Lippincott Company, 1923. Pp. 234. Price, 8s. 6d. net. Obtainable from Messrs. Butterworth & Co. (India), Ltd., Post Box No. 251, Calcutta.

THIS is a fascinating little book written for mothers, nurses, and social workers who have had a moderately good education.

The book begins with a most excellent chapter with photographs on vitamins, and proceeds to instruct as to the physiology of breast feeding and its advantages over any other method.

There are many useful chapters on diet, and on the artificial feeding of young, premature, and sickly infants. Unfortunately most of the foods prescribed are unprocureable in this country.

PRACTICAL ORGANOETHERAPY.—By Henry R. Harrower, M.D. Fourth Edition. London: Endocrines, Ltd., 1922. Pp. 416.

THIS is an extremely interesting book, which will be found of most use to those who are practising physicians and who have not forgotten the intimate connection between physiological principles and clinical signs and symptoms. Dr. Harrower has specialised for the last ten years in producing the various products of the endocrine glands, and is so firm a believer in their potentialities that he has given us a book which from cover to cover is full of interest and suggestion. Dr. Crile, the eminent American physiologist, has stated that the crucible of the clinic is the only reliable method of testing the inherent value of any remedy.

If we are to believe Dr. Harrower, the treatment of 99 per cent. of infirmities is by the application or combination of ductless glands; we can only hope that the optimism of the Harrower Laboratory will prove as well founded as this publication is entertaining.

LECTURES IN MEDICAL JURISPRUDENCE.—By William Nunan, B.A., M.D. Bombay: D. B. Tara-porevala, Sons & Co., 1925. Pp. 162. Price, Rs. 5.

DR. NUNAN of Bombay has written an excellent little book on medical jurisprudence, which embodies his lectures as Professor of Medical Jurisprudence to the Grant Medical College. A short work on this subject was much needed, and his book gives an up-to-date description of the essential facts on which questions are likely to be asked in courts of justice. It is common knowledge that this is a difficult subject for the majority of students, requiring as it does common sense and powers of observation rather than academic information. He lays great stress on the importance of giving clear evidence: to describe the result of a post-mortem fully and clearly in non-technical language is no doubt an art, but it is an art which has to be cultivated in order to achieve success in this field.

He gives a very good instance of the danger of a medical witness expressing an opinion on quotations from books without first seeing the whole context. The quotation was "It is impossible, to a decade, to fix definitely the age of an individual." He, however, asked to see the book, and the concluding words of the sentence were "after the age of 25 years," which of course completely alters the meaning. The whole work is very well done, the chapters on wounds being perhaps the best. We think that a chapter on rape would have been worth including. This book is full of good things very clearly described and we can strongly recommend it both to students and practitioners.

LEPROSY.—By Sir Leonard Rogers, G.I.E., M.D., F.R.C.P., F.R.C.S., F.R.S., I.M.S. (retd.) and Dr. E. Muir, M.D., F.R.C.S. (Edin.). Bristol: John Wright & Sons, Ltd., 1925. Price, 12s. 6d. cloth; 10s. 6d. paper covers. Pp. 301. Illustrations 65.

THE appearance of this book has been looked forward with the greatest interest by all who knew that it was in preparation. Although most of the subject matter has already been published, either in the form of the Croonian Lectures by Sir Leonard Rogers or in articles by Dr. Muir in the medical journals, there has been a keen desire on the part of medical men to have an authoritative and complete account of the whole subject. Great as is the reputation of the authors, it will undoubtedly be enhanced by the book which they have now produced.

The disease is dealt with in a masterly and broad-minded manner and though necessarily much of the book deals with the personal work of the authors, there is never a lack of a sense of proportion and the views of other authorities are fully set forth.

The first three sections are mainly by Sir Leonard Rogers; these comprise a clear and lucid account of the history, distribution, epidemiology and prophylaxis of the disease, while the sections on aetiology, clinical description and treatment are chiefly by Dr. Muir.

Sir Leonard's account of the history and distribution of the disease is the result of immense labour and study, but the narrative is so clear and simple that the reader never has the impression of an encyclopædic work, but rather of a fascinating story. Throughout the pages there runs the thread of purpose; the thread has not first been woven and the purpose made to fit in with the ideas of the author, rather the facts are marshalled and the inevitable deductions are set forth. The contagiousness of the disease is clearly shown by an analysis of 700 cases from the literature; personal association with a leper stands out as the source of the disease in the great majority of cases and the special susceptibility of the young is established. The subject of prophylaxis is dealt with on sober and common-sense lines; the ideal method of early notification and immediate segregation are recognised as being utterly impracticable in most of the countries which are chiefly affected, but a practicable compromise is ably advocated. The chief measures which are discussed are:—

I. Compulsory notification; this is possible only in some advanced communities.

II. Medical Boards are necessary when compulsory measures are instituted. Their object is to secure accurate diagnosis and so to prevent unwarranted restraint of persons who are not lepers.

III. Compulsory segregation, where practicable, is the ideal, but in many countries voluntary segregation must play a large part. It is only in the case of children, who should be protected by law from associating with lepers, and in the case of persons who follow occupations which involve danger to the community that compulsory measures will be practicable in poor and backward countries. Home isolation is rarely successful, but when thoroughly carried out as in Norway, it has proved of great value.

IV. Examination of contacts to detect the earliest stages of the disease is recommended.

The organisation of leper colonies is fully dealt with and the conditions for success are clearly stated.

Leprosy clinics, to which early cases are attracted, are strongly advocated, and in many places these constitute the most hopeful of the practicable means of controlling the spread of the disease. The cure of early cases will attract patients to the centres for treatment and in this way the leper will be kept from progressing to the dangerous infective stage.

An essential factor is that the disease should not be driven underground and that the victims should not be ostracised, lest they be forced to conceal their disease in their own interests. The success of the Calcutta School of Tropical Medicine clinic shows that when patients are convinced that they can obtain relief, they will gladly come for early treatment.

The manner of infection is fully dealt with and though the question remains to some extent open, it is evident that the bacilli enter the body through the skin or nasal mucosa, probably through abrasions which are infected by material containing the bacilli, but possibly to some extent through the bite of some insects.

The important question of early diagnosis is fully and clearly dealt with, and any practitioner who reads this book and makes an honest attempt to follow the instructions which are contained in it should have no reason for falling into the common error of failing to recognise leprosy even in its early stages.

We turned with the greatest interest to the section on treatment, and our most sanguine anticipations have

been fully realized. The subject is dealt with on sane and broad lines, the tendency of the disease to undergo spontaneous cure is frankly stated, the great importance of general hygienic measures, especially of good food, exercise, fresh air and *hope* are emphasised. The doctor is warned that all other causes of ill-health such as syphilis must be thoroughly sought for and suitably treated.

We are not presented with a panacea for leprosy and asked to pin our faith to it to the neglect of everything else, but rather to attend first of all to the factors which help leprosy to progress and then to call in the valuable aid of the special forms of treatment which the authors have done so much to establish.

We have searched in vain for evidences of the unjustifiable optimism which has sometimes been attributed to exponents of the newer treatments; instead of this we have found an honest statement of what can be done and of what cannot be done by treatment.

It must be emphasised that all cases of leprosy are not curable; only patients who come for treatment early have any right to expect that their disease will be controlled, and even these must expect to continue treatment for long periods. Another point is that the treatment does not consist merely in the perfunctory giving of injections, but in the intelligent and persistent following up of each case and the adaptation of the treatment to the special needs of each patient.

Granted the combination of skill, perseverance and optimism, better results may confidently be hoped for than in cases of tuberculosis of similar severity; no one has any right to condemn as useless a line of treatment which he has neither understood nor tested.

Sir Leonard Rogers and Dr. Muir are still up against a hard task, but what they have already accomplished makes it easy to predict that nothing short of insane opposition on the part of the medical profession can prevent them from continuing on their victorious path.

The issue of this admirable book ought to play a great part in the waking up of the medical profession in India in the matter of leprosy; it appears at a very opportune time when an appeal is being made for the vigorous prosecution of a great campaign against the disease.

A KEY TO ANOPHELINE MOSQUITOES. A GUIDE TO THE RAPID IDENTIFICATION OF BOTH SEXES OF THE SPECIES OF INDIA, CEYLON AND MALAYA.—By C. Strickland, M.A., B.Ch. (Cantab.), Professor of Medical Entomology, Calcutta School of Tropical Medicine,—late Travelling Medical Entomologist, F. M. S. Government. Calcutta: Messrs. Thacker, Spink & Co., 1925. Pp. 13. Illustrated with lithographs, line blocks and text figures. Price, Rs. 2.

THIS admirable and excellently executed little work meets a long felt want. There are already several classifications of Indian anophelines extant; but some are tomes of considerable volume, others long series of articles in medical research journals, others scanty and non-illustrated tables on flimsy paper, liable to tear. This work is different; it is handy in size, complete, yet concise and lucid, easy for reference and admirably printed, whilst two beautifully executed colour plates illustrate the wing venation. Dr. Strickland on his title page quotes his modest aim—from the "Hunting of the Snark"—to be as follows:—

"It next will be right

To describe each particular batch,
Distinguishing those that have feathers and bite
From those that have whiskers and scratch."

In classification and identification Dr. Strickland relies mainly upon wing markings and the markings of the hind leg; the diagnosis being equivocal in only a few cases in which a reference to other structures is necessary. The illustrations are profuse and exceedingly well executed.

This little brochure will prove invaluable to many different classes of workers; to medical and post-graduate students, to medical officers, to malarial survey officers, and to tea garden doctors. The authoritative position which its author holds in this particular field is well known, and both he and the publishers are to be congratulated on the "next step forward" in medical entomology in India.

THE PNEUMOCOCCUS AND PNEUMOCOCCAL AFFECTIONS.—By L. Cotoni, C. Truche and Mille. A. Raphael. English edition by D. S. Page, M.A., M.B. (Cantab.), D.P.H. and Eva Morton, M.R.C.S. (Eng.), L.R.C.P. (Lond.). London: John Bale, Sons and Danielsson, Ltd., 1924. Pp. 218. Price, 16s. net.

THIS monograph of some 200 pages represents a summary of the researches on pneumonia carried out in Nicolle's laboratory since 1908.

The subject is taken up under three headings:—(1) The pneumococcus; (2) Diseases of pneumococcal origin; and (3) The treatment of pneumococcal diseases.

In the first part the bacteriological aspect of pneumonia is thoroughly dealt with. The essential characters of the pneumococcus, the difficulties encountered in differentiating this organism from streptococci, and the relation between virulence and solubility in bile are clearly defined. The chapters on the types of pneumococci and the properties of anti-pneumococcal serum introduce a good deal of controversial matter, and explain the views held by the French in contrast with those of the American workers.

The second part of the monograph is well written and contains an invaluable section on the crisis in pneumonia in its clinical, biochemical and serological aspects.

The concluding chapters deal with specific therapy in pneumococcal diseases. The authors claim a large measure of success in the use of anti-pneumococcal serum prepared at the Pasteur Institute of Paris.

Prophylactic vaccination, vaccine therapy, and chemotherapy are only lightly touched upon.

The monograph contains a good bibliography.

Annual Reports.

ANNUAL REPORT ON THE HOSPITALS AND DISPENSARIES UNDER THE GOVERNMENT OF BENGAL, 1923. CALCUTTA: BENGAL SECRETARIAT BOOK DEPOT, 1924. PRICE, RE. 1.

MAJOR-GENERAL B. H. DEARE, C.I.E., I.M.S., was Surgeon-General with the Government of Bengal, except during the period 10th April to 24th November, when Lieutenant-Colonel D. McCay, M.D., I.M.S., and Lieutenant-Colonel A. B. Fry, C.I.E., D.S.O., M.D., I.M.S., held charge in turn.

Calcutta Hospitals and Dispensaries.—Twenty-four such institutions were working at the commencement of the year, and two more were opened during the year, viz., the Entally and Taltolla Municipal Dispensaries; 2,903 beds for in-patients being available during the year in the 17 institutions concerned. 40,755 in-patients and 375,264 out-patients were treated during the year, there being an increase in the number of in-patients as compared with former years, but a decrease in out-patients owing to the institution of charging small fees in the Medical College, Campbell, Sambhu Nath Pundit and Presidency General Hospitals. The death-rate among in-patients was much the same as in former years, 11.26 per cent.

Cholera was of mild character during the year; 1,402 in-patients with 274 deaths. Kala-azar shewed again a very marked increase; 5,599 patients treated as against 2,940 in 1922,—the results of increasing popularity in the antimony treatment and of more patients coming forward for diagnosis and treatment. Malaria was responsible for some ten per cent. of patients treated, whilst small-pox and influenza were of but little importance. Tuberculosis is of increasing importance; 3,251 patients as against 2,595 in 1922; whilst the incidence from venereal diseases is almost stationary. Surgical operations performed numbered 44,052, and important and selected surgical operations 7,731. A special report on the work of the Eden Hospital for the year shews how large a volume of obstetric and gynaecological work is carried out; 1,147 cases of confinement during the year with 32 deaths; and 567 major gynaecological operations.

The total income of hospitals of classes I, III and IV was Rs. 28,79,872, a decrease of Rs. 29,560 on the figure for 1922,—government contributions totalling 65 per cent. of this income. The total expenditure was Rs. 27,78,230, a substantial decrease on the 1922 figure. Careful and rigid—if almost meticulous economies—secured a substantial reduction in the expenditure on both medicines and diets;—a decrease perhaps admirable from the point of view of provincial finances, but deplorable from the point of view of the comfort of patients and staff.

District Hospitals and Dispensaries.—The number of these increased from 859 in 1922 to 914 in 1923, of which 27 were homeopathic dispensaries and 13 Ayurvedic dispensaries. In the western medical institutions 7,082,603 patients were treated during the year; no less than 2,101,954 of them for malaria. In-door patients numbered 61,975 with a mortality of 6.38 per cent. Influenza, cholera and small-pox were unimportant during the year, but venereal diseases and tuberculosis shewed an increase. Kala-azar shewed an increase to 34,264 patients treated as against 15,566 in 1922, as the result of better and earlier diagnosis and the greater willingness of patients to come forward for treatment. Mymensingh,—previously regarded as not infected,—is now known to be an endemic centre. The figures for leprosy also shewed an increase from 2,189 to 4,144 patients treated, for similar reasons. The total number of surgical operations numbered 132,409, and selected operations numbered 5,831.

Financially, the income of hospitals, etc., of classes I, III and IV was Rs. 19,77,842 as against Rs. 17,77,990 in 1922; and the expenditure Rs. 18,30,417 as against a corresponding figure of Rs. 17,44,891. Local funds contributed 47 per cent., and government funds 13 per cent. of the income. Subscriptions and donations realised nearly 19 per cent. of the income received.

The year was remarkable in fact for the rapid increase in the number of district and union board dispensaries, but the question of personnel still remains unsatisfactory; officers of assistant surgeon class having in many instances been replaced by sub-assistant surgeons; and the latter by private practitioners. The introduction of the practice of charging small fees has not been popular; whereas in some districts it has led to an increase in income, in others it has seriously interfered with the collection of subscriptions.

On the whole, the report records steady, but not remarkable increase in the medical and surgical facilities in the Province.

CONTAGIOUS DISEASES HOSPITAL AND MUNICIPAL OBSERVATION HOSPITAL, RANGOON. ANNUAL REPORT FOR 1923. BY DR. K. R. DALAL, L.M. & S. (BOMBAY), D.T.M., D.P.H. (L'POOL). RANGOON: THE TIMES PRESS.

The annual reports of these two hospitals are always interesting reading, as with a small staff and amid much hard work, Dr. Dalal manages to collect together

for publication many interesting clinical observations. In our review of his report for 1922 we commented on the scandal of having no electric light in a contagious diseases' hospital where intravenous transfusions for cholera may have to be given at any hour of the night; this year we are glad to read that electric light has been installed in the cholera ward (only) of the hospital; the reason for the apparent parsimony in not providing it throughout the whole hospital is that "there is every probability of a new contagious diseases' hospital being erected in the near future." We trust that the "near future" will not become the Greek calends, for a new and up-to-date hospital is apparently much wanted.

A second improvement during the year was the provision of a new separate latrine and separate washing and bathing platform for small-pox patients; and Dr. Dalal's mention of this leads us to wonder in how many infectious diseases' hospitals in this country do small-pox patients use the same latrine and washing and bathing places as the other patients in the hospital. It is all very well to segregate cases of infectious disease; but to compel the unfortunate victims of different infectious diseases to use the same latrine and bathing place is a little harsh. Fortunately, the year saw a small-pox epidemic in Rangoon, with resulting improvements in the hospital. As Dr. Andrew Balfour has pointed out in "Health Problems of the Empire" it usually takes the stimulus of fear of a present epidemic to secure sanitary reform on the part of municipalities. However, we do not suppose that it is any more risky to use a latrine recently visited by a small-pox patient, than to sit next to a small-pox patient in a Calcutta tram.

In commenting on the provision of staff, Dr. Dalal raises a thorny and difficult problem. In non-epidemic times all is *laissez faire* and matters jog along comfortably; a half empty hospital and a contented staff and establishment. When an acute epidemic of infectious disease breaks out, however, extra temporary staff has to be entertained,—often on a large scale,—and this temporary staff is wholly untrained; "the corporation has sanctioned on a liberal scale employment of extra hands in times of epidemic and sudden emergencies, but in actual practice it has been found extremely difficult to secure efficient hands in time to meet the increased demand," with the result that most of the extra strain falls upon the small permanent staff. On a larger scale, in connection with public health matters, this problem has been solved in the Madras presidency; the epidemiological staff is there and in training in the non-epidemic times, the services of its members being utilised in vaccination and other duties; once the epidemic commences they can be rapidly mobilised and are already trained. In connection with Dr. Dalal's hospital, we note that there is no reserve of any kind, not even a leave reserve, whereas in the official government services in India the leave reserve usually stands at a figure of 20 to 25 per cent. An increase of staff and establishment by some 25 per cent., we suggest, would be a useful measure of insurance against times of epidemics in such cases. Further, the best time to raise such suggestions is in the middle of a severe epidemic; once such an increase is sanctioned, it becomes the order of the day,—a precedent, something which cannot be altered.

During the year 1,535 patients were treated; the chief diseases concerned being small-pox, 609 cases; plague, 281 cases; and chicken-pox, 208 cases. The figure for chicken-pox is very interesting in view of the recent suggestion by several authorities that small-pox, "alastrim," vaccinia and chicken-pox are all in reality but modified strains of the same virus; some of these cases of chicken-pox, however, may possibly have merely been very mild small-pox. Male patients totalled 1,341 and females 194, whilst 1,205 of the patients were sent in by the public health authorities, and 330 were voluntary admissions. The total death-

rate from these severe diseases was 26.4 per cent., a figure which is very good when one considers how many moribund patients are sent to such hospitals; already dying of small-pox, plague, cholera or the like.

There were 285 admissions for plague during the year, with 187 deaths, but more than half the cases admitted were admitted on the 3rd or later day of illness, and 55 cases died within the first 24 hours of admission. Only 2 of the cases were of pneumonic type, but plague was present in Rangoon throughout the whole year, admissions occurring in every month from January to December.

Cholera was of but little importance, and accounted for 41 admissions with 24 deaths, including 2 cases found dead when the ambulance reached the hospital, and 12 other cases, more or less moribund on admission.

Small-pox accounted for 626 admissions, and was present throughout the year, but especially prevalent in March and April. Of the 626 cases, 343 had been vaccinated, and 38 of these died; a case mortality rate of 11 per cent.; whereas of the 283 unprotected cases 115 died, a case mortality rate of 43.6 per cent. There were no deaths in the modified and discrete cases, but mortalities of 39 per cent. in the confluent cases, and 89 per cent. in the hæmorrhagic ones. A table of incidence of small-pox during the past 13 years in Rangoon shews how the epidemic waves appear to recur every fourth or fifth year.

There were 95 cases of influenzal pneumonia admitted during the year, most of them sent in by the port health authorities in a very bad state from incoming vessels. The death-rate was 18 per cent., a low figure considering the adverse conditions present. Fourteen patients were sent in with a diagnosis of plague, but proved on examination to be simple adenitis.

The total cost of the hospital was Rs. 65,773, of which Rs. 16,585 was spent in diet and Rs. 748 on sera and vaccines. Dr. Dalal comments on the high cost of anti-sera in India,—a matter of constant trouble to all hospital superintendents in this country.

Turning to special lines of treatment, cerebro-spinal fever is treated by lumbar puncture plus intrathecal injection of a polyvalent serum. The results were rather disappointing, 19 deaths in 23 cases; but the local strain of meningococcus requires to be investigated and typed in order to get the right serum. Intramuscular injection of calcium chloride proved useful in hæmorrhagic small-pox; whilst the use of Sir Archdall Reid's powder,—aspirin, grs. x.; phenacetin, grs. v.; and pulv. ipecac. co., grs. v.,—has been found useful in pneumonia and in small-pox. Despite the fact that many moribund cases were admitted the mortality in the plague cases was 65.6 per cent. as against a general case mortality rate of 96.8 per cent. for Rangoon in general. The question of serum treatment for plague was raised by a correspondent in the local papers during the year, but Dr. Dalal is not convinced that serum treatment is worth while, and quotes the following figures:—

CASE MORTALITY,
PER CENT.

	Treated with serum.	Not treated with serum.
	p. c.	p. c.

British Commission; 1913.		
222 cases treated; 222 controls ..	66.2	73.9
Dr. Choksy.		
200 cases; 200 controls ..	63.5	74
Rangoon hospital, 1922	66.7
Rangoon hospital, 1923	65.6

Finally, an encouraging feature of the work at the Contagious Diseases Hospital is the increasing number of patients who come in voluntarily for treatment; these having numbered 21.5 per cent. in 1923.

At the Municipal Observation Hospital, which serves solely as an observation hospital for cases sent in from incoming steamers, there have been extensive structural alterations during the year, consequent on the operations of the Rangoon Development Trust; 2,495 persons were under observation during the year, of whom 64 per cent. were discharged as shewing no appreciable disease, after observation.

ANNUAL CLINICAL REPORT OF THE GOVERNMENT HOSPITAL FOR WOMEN AND CHILDREN, MADRAS, 1923. BY LIEUTENANT-COLONEL C. A. F. HINGSTON, O.B.E., I.M.S., SUPERINTENDENT, GOVERNMENT PRESS, MADRAS, 1924.

THIS report follows the usual lines and shews what good work this institution continues to do. 2,841 obstetric cases and 3,379 gynæcological ones were treated during the year. There were 2,768 deliveries with 72 maternal deaths,—32 from accidents of child-birth, chiefly adherent placenta; 8 from puerperal septicæmia; and 32 from non-puerperal causes, chiefly anæmia; whilst the fact that only 2 deaths occurred from post-partum hæmorrhage speaks well for the care taken in conducting deliveries.

There were 40 cases of eclampsia among primiparæ and 24 in multiparæ, a total of 64. Of these no less than 36 were delivered by natural means, and 23 out of the 62 children were born living. The maternal deaths numbered 7, a mortality rate of 11 per cent. The blood pressure readings in some of these eclampsia cases were as high as 200 mm. and veratrine was freely used.

Of the 2,768 deliveries, 1,518 were natural; 371 difficult; 69 preternatural; 652 complex; with 158 abortions, of which 131 were incomplete. A table shewing the classification of obstetric operations resorted to gives some interesting figures as to the different indications for each; thus vertex presentation with difficult labour constituted the chief indication for podalic version with extraction; breech and foot presentations the chief indication for podalic extraction; and prolapse of the cord the chief indication for perforation of the head. There were 23 Cæsarian sections; 19 of them for prolonged and difficult labour, and 1 for eclampsia.

The total number of confinements shewed an increase of 40 cases over the figure for 1922, and was the largest on record in the hospital. Primiparæ numbered 27 per cent. and the number of confinements monthly varied from a minimum of 198 in April to a maximum of 271 in November. Hindu patients constituted 37 per cent., Europeans and Anglo-Indians 11 per cent., and Mahomedans only 2 per cent. In natural non-difficult labour, with a vertex or face presentation, the average duration of labour in 1,518 cases was 11.38 hours in primiparæ, and 8 hours in multiparæ. There were 52 cases of plural births, including a case of triplets; and 2,610 labours (excluding abortions) gave 2,658 children, of which 2,102 were full term.

On the gynæcological side, much operative work was carried out, including 122 uterine ventro-fixations.

Colonel Hingston is to be congratulated on the increasing sphere of usefulness of the hospital, and the accumulation of observed facts on which to base improvements in technique and procedure.

ANNUAL REPORT OF THE UNION MISSION TUBERCULOSIS SANATORIUM, AROYA-VARAM (NEAR MADANAPALLE), S. INDIA, 1923-1924. MYSORE: WESLEYAN MISSION PRESS. 1925.

As yet but little in the way of organised effort is being put forward to deal with the terrible problem of tuberculosis in India,—a problem probably far more severe in India than in temperate climates. To this

rule, the report of the Union Mission Sanatorium at Madanapalle, and those of a few kindred institutions form honourable exceptions. The sanatorium was founded in 1912 and is maintained through the efforts of fourteen different missions. It covers 100 acres of ground, with more than 70 buildings, spacious grounds, and has a clear atmosphere free from dust. The climate is dry, with an average rainfall of only 28 in., and a temperature not exceeding 80° F. in the cold weather, and 102° in the hot weather. The institution also receives an annual grant of some Rs. 26,000 out of its total expenditure per annum of Rs. 96,000 from the Government of Madras. It is under the charge of Dr. C. Frimodt-Møller, M.B., Ch.B. (Copenhagen). The total available accommodation amounts to 140 beds.

During the year under review, 227 patients were admitted and 211 discharged, the daily average attendance being 128, with a long waiting list and the available accommodation taxed to its utmost capacity. Hindu patients predominate, but all races and castes are represented, as well as a miscellany of occupations and of ages ranging from 6 to 50 years: 66 per cent. of the patients came from the Madras Presidency.

Of the 211 cases discharged during the year, 45 had spent less than a month in the sanatorium, and may be excluded from the figures,—leaving statistics available for 166 cases. Of these 14 per cent. were in stage I when admitted; 26 per cent. in stage II; and no less than 60 per cent. in stage III; shewing how severe is the ordinary case of tuberculosis when admitted to hospital in India. Of these 166 patients, 34 were discharged with the disease arrested; 45 as much improved; and 39 as improved. Of stage I patients, 100 per cent. shewed improvement or arrest of the disease; of stage II patients, 88 per cent.; of stage III patients, 57 per cent. The average increase in weight in the whole group of 166 patients was 12 lbs.

Dreyer's vaccine was tried on 31 of the discharged patients. The conclusion is come to that the vaccine at least did no harm; all the cases treated were in stage III; and 4 were discharged as much improved and 16 as improved. Artificial pneumothorax was tried in 12 cases, but—owing to adhesions—only succeeded in 6 cases. This measure is only tried in cases which respond to no other form of treatment; hence the result of 5 cases definitely improved or much improved is very satisfactory.

During the year the laboratory facilities were extended, and biological section added; improvements to buildings and to the conservancy system were carried out; and two new special wards constructed. The whole report, in brief, tells of steady progress in the attempt to tackle one of India's most serious disease-problems, albeit on a small scale.

ADMINISTRATION REPORT ON THE JAILS OF THE BENGAL PRESIDENCY, 1923. BY LIEUTENANT-COLONEL F. S. C. THOMPSON, O.B.E., I.M.S., CALCUTTA: BENGAL SECRETARIAT BOOK DEPOT, 1924. PRICE, RS. 10-8-0.

IMPROVEMENT in several directions characterised the year in the jails in Bengal. The death rate, 15 per mille, reached the lowest figure ever recorded for the jails of the province, thanks to such measures as chlorinating the water supplies, fly-proof enclosures for cooked food, etc. Further, more space was available, as the daily average number of prisoners fell by about 1,500 as compared with the previous year, and political prisoners only numbered 33 at the end of the year.

Further recommendations of the Jails' Committee were brought into force, extra clothing having been provided for both male and female prisoners, rules framed for better hospital administration, female prisoners having been granted the concession of retaining

their children with them up to the age of 4 years, religious privileges being granted to Sikh and Mahomedan prisoners, and rules for the separation of adolescents guilty of grave crimes having been revised. The scale of dietaries was improved and rules regarding jail offences were revised,—solitary confinement being abolished.

Comment has been made by several Superintendents on the evils of the prevalent practice under the revised sections 109 and 123 of the Criminal Procedure Code of sending prisoners to simple imprisonment for failure to give monetary security. Discipline was far more satisfactory in 1923 than in the previous few years, and to a large extent the attacks on and misrepresentations of jail administration by various newspapers had ceased. Tobacco is permitted to under-trial prisoners at their own expense, and Colonel Thompson considers that a judicious issue of tobacco to other prisoners as a reward for good conduct would be of assistance in maintaining discipline.

Urgent needs of the department, however, are an habitual jail, a Borstal institution for the segregation of youthful offenders from habitual prisoners, more prisoners' aid societies, and better lighting in the jails.

The average daily strength was 15,220, of whom only 195 were females, 57 per cent. of admissions during the year were Mahomedans, and 38 per cent. Hindus. The decrease in the number of juveniles admitted during the year was satisfactory; only 310 persons below 16 years of age having been committed to prison during the year; this old-standing scandal therefore now at last appears to be dying out. Some 10.7 per cent. of those admitted were able to read and write.

The Juvenile Jail at Alipore continued to function rather as a disciplinary school than as a jail. The daily average number of juveniles in the jail was 195, but had dropped to 179 at the end of the year. In this connection Colonel Thompson again dwells upon the harmful results of short term imprisonment on young boys of 15 years of age and less; such sentences defeat the reformatory objects of the jail, since the boys are not imprisoned for a sufficiently long period to become well trained, whilst often they are of such a tender age that they should never have been sent to jail at all. In this institution no corporal punishment was given,—a marked contrast to such a "free" institution as an English public school. Physical training, Swedish drill and games play a large part in the scheme, whilst religious instruction is provided for the different castes present by their own moulvies or priests. There is some difficulty, however, in the after-care of released juvenile prisoners.

About one-third of the prisoners admitted during the year had received sentences not exceeding one month. These sentences are perfectly useless and harmful from every point of view. They are too short to act as a deterrent to crime and are never reformatory; on the other hand, they are sufficiently long to lead to the mingling of such short term prisoners with habituals of the most undesirable class, who encourage them to a career of crime. In fact, such sentences do more to stimulate rather than to lessen crime; but magistrates have still to realise the lesson. Re-convicted prisoners numbered 23 per cent., which about represents the proportion of habituals among the general jail population; habituals, identified as such, numbered 20 per cent.

Under-trial prisoners during the year numbered 36,375, of whom 10,369 were convicted. The periods of detention of such persons varied from an average of 41 days in sessions cases to 18 days in all other cases.

Turning to the warder guard, conditions show some improvement, and it is high time that they should. The number of resignations shewed a considerable decrease on previous years, and the pay is now the same as for police constables of corresponding rank and length of service. Dissatisfaction continues, however, with

reference to such matters as the supply of uniforms and undress kit, railway and concession passes when on leave, etc., and a memorial has been submitted to government.

During the year there were 13 escapes, 10 of them from outside the jails, and 6 of these from jail gardens. The rules regarding the employment of convicts as prison officers,—convict warders,—were revised during the year and the system is reported to have worked very satisfactorily; until funds permit it is impossible to do away with this system, but, on the whole, it is a satisfactory one.

Financially, the total expenditure in the department during the year was Rs. 24,04,832, which represents a saving of over 4 lakhs on the figure for the previous year. A net cash earning of Rs. 4,35,715 was contributed to government revenues, chiefly by the Dacca Central, Alipore Central and Midnapore Central Jails. The Presidency Jail deals largely in jute products, furniture and ironmongery; the Alipore Central Jail prints and supplies official forms; the Midnapore Central Jail is chiefly engaged in tailoring, and a dyeing industry was started in this jail during the year. Dacca Central Jail also manufactures blankets and uniforms, whilst the Alipore Juvenile Jail dealt with 13,044 lbs of quinine sulphate, and cinchona febrifuge.

Turning to the sickness and mortality tables, it is interesting to note how the figures given correspond to those for the province in general. Malaria was the chief cause of sickness,—3,532 admissions with 20 deaths,—but tuberculosis was the chief cause of deaths 154 admissions with 37 deaths. Dysentery, with 1,082 admissions and 27 deaths, ranks third in importance; and diarrhoea, 1,081 admissions with 4 deaths, next. The only other important cause of sickness was abscesses and boils, etc., 959 admissions with 1 death; whilst cholera was virtually absent,—5 admissions with 2 deaths. This last figure, among a daily average population of 15,220 is striking testimony to the efficiency of jail sanitation in the province. The relative infrequency of pneumonia, 122 admissions with 22 deaths, also bears testimony to the care with which prisoners are looked after and nursed when ill.

Government gazetted holidays observed, in addition to Sundays, numbered 9 as against 3 the previous year; whilst on the big festival days extra food is allowed to all prisoners.

Colonel Thompson is to be congratulated on a year of steady progress and improvement of conditions. In brief, we believe that any impartial enquirer would find that jail conditions in India compare not unfavourably with those in England, and are probably better than those in many European States.

ADMINISTRATION REPORT ON THE JAILS OF BIHAR AND ORISSA, 1923. BY LIEUTENANT-COLONEL W. GILLITT, C.I.E., M.D., I.M.S. PATNA: GOVERNMENT PRINTING, BIHAR AND ORISSA, 1924. PRICE, RS. 2.

Two of the chief events of the year were the conversion of the adult portion of the jail at Monghyr into a subsidiary jail, and the opening of a new subsidiary jail at Jamshedpur; thus changing the number of central and district jails to 17, and of subsidiary jails to 48. The daily average population under confinement was 5,956, and this figure included 191 prisoners from the North-West Frontier Province, taken over by the Government of Bihar and Orissa, owing to over-crowding in the jails of the former province. Of the daily average of 5,956 prisoners, females numbered 118 only.

Youthful offenders under 20 years of age numbered 485, including 47 boys and 1 girl under 15 years of age. The daily average population at the juvenile jail numbered 122, and arrangements have been made in conjunction with the Education Department to hold regular

inspections to test the value of the training given. Technical classes are held in weaving, carpentry and smithy,—the first being the most suitable industry for a boy who has afterwards to make his way in the world. Drill, gymnastics and wrestling and other games are taught for one hour daily, whilst the formation of a Juvenile Prisoners' Aid Society at Monghyr is an event which should help in finding employment for discharged prisoners.

Of 11,495 prisoners admitted during the year, 27 per cent. had received sentences not exceeding one month, and 29 per cent. sentences exceeding one month but not exceeding three months; these figures are very bad, as they indicate the possibility of some 50 per cent. of first offenders mingling with habitual and hardened criminals for just long enough to imbibe their ideas and ways. The Local Government have drawn the attention of magistrates to the harm done to juvenile prisoners by sentences of 15 days or less,—of whom 38 were admitted during the year.

Colonel Gillitt complains of the revision under which simple imprisonment can be awarded under section 109 of the Criminal Procedure Code, and fears that it will mean an increase in the number of prisoners admitted to simple imprisonment in default of finding monetary security. "Simple imprisonment has little to commend it at any time; to give it to habitual criminals of the worst type is distinctly dangerous; they indulge in behaviour subversive of jail discipline and also lay their plans for future crimes after release." Habitual prisoners numbered 11.7 per cent. of those admitted during the year. The Central Jail at Buxar has been set aside for the confinement of this class of prisoners, but has been found to be inadequate; so a part of the Bhagalpur Central Jail has been utilised for the purpose.

Under-trial prisoners averaged a daily strength of 921. Of the total number only 30 per cent. were convicted, the average period of detention being 39 days in sessions cases and 22 days in other cases. Civil prisoners admitted during the year numbered 146, and political prisoners only 9, whilst 49 non-criminal lunatics were sent to jail for observation,—in accordance with the old-standing, but none the less dreadful, custom in India. The Indian Jails' Committee long ago reported on the evils of this custom of sending non-criminal suspected lunatics to jails for observation, and on the agonies which such patients undergo when they realise their surroundings; but until mental detention wards can be provided in the chief hospitals in India, we suppose that this barbarous custom will continue to prevail.

Escapes from jail numbered 15, 10 of them among under-trial prisoners. This included 3 under-trial prisoners who escaped from Bhadrak Subsidiary Jail with the help and connivance of their warder guard. Ten of the 15 were re-captured. With regard to classes of prisoners, it is noted that no less than 36 per cent. were returned as habituals. Whippings are but rarely resorted to in jail discipline,—26 instances; and fetters in only 88 instances. An average of 210 male and 4 female convicts were employed as prison officers out of a total average population of 4,903 male and 118 female prisoners. The strength of the warder guard was increased from 1,185 to 1,190.

Financially, the total cost of the department during the year was Rs. 11,53,374, or Rs. 25,920 less than in the previous year. On an average 4,894 prisoners were employed daily, and the total cash earnings during the year amounted to Rs. 1,72,703. In Buxar Jail tents are manufactured, and there are large tailoring and weaving departments; at Bhagalpur blankets are made, and proposals have been made for the re-organisation of this factory; at Gaya the official forms press absorbs most of the labour available; whilst at Hazaribagh, the manufacture of aloe goods, oil-pressing, cotton weaving and tailoring are the chief industries.

Turning to vital statistics, the ratio of admission to hospital was 39 per mille, and the total deaths 116 out of a total population of average daily strength 5,956 as against a corresponding figure of 100 in 1922. The death rate per mille was 19.4, mainly due to the unhealthiness of Gaya Central Jail, where one-third of the total deaths took place, with a ratio of 50.4 per mille. The chief causes of death were dysentery, pulmonary tuberculosis and pneumonia, but several of these occurred—as usual—among prisoners who were in a bad state of health when admitted. Dysentery was unduly prevalent in Bhagalpur Central Jail, and the Director of Public Health has been asked to undertake an investigation into the prevalence of this disease in the chief jails of the province. Examinations of prisoners' stools for hookworm ova were continued during the year, and 54 per cent. of prisoners found to be infected; apparently ankylostomiasis is an important factor in the incidence of intestinal diseases in the jail population in the province. Leper prisoners are all removed to Muzaffarpur Jail, where there is separate provision for them. It is of interest to note that of the 12,942 prisoners discharged from central and district jails during the year, no less than 57 per cent. had gained in weight since admission.

ANNUAL REPORT OF THE CHEMICAL EXAMINER'S DEPARTMENT, BENGAL, 1923. CALCUTTA: BENGAL SECRETARIAT BOOK DEPOT, 1924. PRICE, 12 ANNAS.

MAJOR T. C. BOYD, F.R.C.S.I., D.P.H., I.M.S., was in charge throughout the year, and 5,557 articles were examined as against 4,293 in 1922. An interesting feature of the year's work was the abolition of the telephone connection, granted in 1906 and of great advantage to the department, but abolished in 1923 on the mistaken grounds of economy; the next time that an important and urgent report on a suspected case of poisoning is urgently required by the courts or other authorities, we suppose that it will be obtained through the usual leisurely "channels of approach."

In the general department, 1,577 examinations were made as against 1,331 in 1922. Of various interesting analyses carried out, several samples of opium were assayed, 1,080 samples of cocaine were examined—a marked increase on the figure of 826 samples for 1922,—and carbon tetrachloride and quinine sulphate samples were examined as to purity. Opinions were asked for as to such divergent facts as the best type of container for quinine tablets, the toxicity of antimony tartrate solutions on keeping, the purity of glucose samples for intravenous injections, the composition of certain cartridges said to produce insensibility, the purity and suitability of samples of chloroform for anaesthesia, and the suitability of samples of methyl alcohol for preparation of Romanowsky stains. A study has also been made of the possibilities of local preparation of liquid extract of ergot and of Indian insulin.

In the medico-legal department, 1,811 cases were examined into as against 1,486 in 1922; the total of work carried out in this department being almost double that for 1921. Stain cases and cases of human poisoning have largely increased of recent years. In cases of human poisoning opium comes easily first as a poison, detected in 12.5 per cent. of visceral specimens examined. It is of interest to note that poisons were detected in 44 per cent. of specimens coming from Native States as against a figure of 19 to 36 per cent. for different divisions in British India. Aconite, arsenic and atropine were the three most common poisons detected in vomited or excreted matter. In only 62 specimens of viscera sent for analysis as to the possible presence of poisons did the medical officers concerned give it as their definite opinion that death was due to poisoning. In 501 such cases the medical officers concerned withheld their opinion as to the true cause of death; a

sufficient indication of the importance and responsible character of the work carried out by the department.

Turning to animal poisoning, the viscera of 100 horned cattle were received during the year, and poison detected in 48 per cent. of them. Aconite, arsenic and aloes are the favourite poisons employed, occasionally atropine and mercury. Blood-stain specimens numbered 1,422 in connection with 451 cases. Blood was detected in 741 of the articles, and that of human origin in 583 of them; 426 suspected seminal stains were examined.

Of several interesting cases recorded, one is an instance of two persons poisoned by oral administration of illicit cocaine; an Anglo-Indian adult female patient took a teaspoonful of strychnine at 5 a.m. after a quarrel with her husband, but lived for an hour and a half afterwards; a suicidal case shewed previous administration of oleander prior to suicide by hanging; oleander was detected in the burnt viscera of two female bodies which had been burnt; a fatal case of oleander poisoning from the medicine of a Kaviraj is recorded; also of fatal aconite poisoning in two cases from administration of aconite in pills prescribed by an itinerant quack; whilst a well known recent medico-legal case where liquid extract of nuxvomica was dispensed by mistake in place of liquid extract of ergot, notes of which are here recorded, will be within the recollection of many in India.

Correspondence.

B. COLI INFECTION IN THE PUERPERIM.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I write with regard to the frequency of *B. coli* infections in the puerperim in India; I have recently had two such cases. The first was a European lady, a primipara; she had a straight-forward labour,—vertex position, with no vaginal examinations made, no douching or other interference. The puerperim was quite normal for ten days with no rise of temperature, even to 99° F. She got up on the tenth day and had retention of urine that night, for which the nurse passed a catheter. Six days later she was dead of acute sepsis. The catheter specimen of urine shewed renal epithelial cells, a few pus cells, abundant *B. coli*, and albumin. The lochia were sterile. Indeed I only found out by accident that the nurse in question had, immediately before attending the patient, been attending a similar acute renal-infection puerperal case with severe fever lasting for six weeks and ending in recovery, and had used the same catheter on both patients.

The second case I saw recently in consultation. She was a Goanese multipara who had had symptoms of bacilluria before childbirth. She had fever for a few hours after the child's birth and died with a temperature of 106° F. on the 21st day. The urine resembled that of the first case. The lochia were not examined bacteriologically, but appeared to be normal.

In my experience as Assistant Master at the Rotunda Hospital in Dublin, I never came across such a case, nor have I read of one, nor can I find any description of such cases in the ordinary text-books. Are these cases common in India? Bacilluria itself is very common in Karachi and I have attended several puerperal women who suffered from the pyelitis of pregnancy. But I feel at a loss with regard to this disease. The usual treatment for bacilluria and sepsis in the first of my cases proved useless; in the second it produced a temporary improvement only.

I hope that some of your readers of larger experience than my own will be able to say whether this form of puerperal sepsis is or is not common in India, and

what measures should be taken to prevent or to treat it.—Yours, etc.,

G. T. WRENCH, M.D., B.S. (Lond.).

VICTORIA ROAD, KARACHI,
26th March, 1925.

INTRAVENOUS PITUITRIN.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I have read with interest the notes of a case of alarming symptoms following an injection of pituitrin in the puerperim by Dr. S. Serhachar, which he ascribes to probable pulmonary embolism, in your issue for March 1925. I have had two exactly similar cases, but with the addition of colicky pains in the abdomen and pelvis. These symptoms are apt to be overlooked in the presence of puerperal or other over-shadowing symptoms, but the patient recalls them in her calmer moments.

In my first case the injection was given intravenously, and the train of symptoms so well described by Dr. Serhachar immediately followed, but subsided within a few minutes. Being in doubt as to the cause of the sudden appearance and disappearance of such acute circulatory and abdominal symptoms, I took an early opportunity of testing pituitrin intravenously in a second case, a normal female patient with intestinal stasis. The result was the same.

Pituitrin is not for intravenous use. It is a potent drug, and the further it is kept from a vein the better. Possibly Dr. Serhachar may have accidentally injected it into a vein, with the result of the dramatic symptoms described. Amyl nitrite capsules, in my experience, may be relied upon in such cases to cut short the distressing and acute symptoms following upon such an injection.—Yours, etc.,

D. M. VASAVADA,
Assistant Surgeon.

BIKANER,
20th March, 1925.

A LARGE CALCULUS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—A large stone, weighing 5½ ounces, was recently removed by Major C. H. Reinhold, M.S., F.R.C.S., I.M.S. from an adult male patient in this district, with a history of symptoms of nine years' duration. The stone was hard and required five evacuations and took one and a half hours for removal. This is the largest stone removed by litholapaxy at this hospital. Will you or one of your readers kindly let me know what is the largest stone to have been removed by this method?—Yours, etc.,

S. SINGH, P.M.S.

LUDOVIC PORTER HOSPITAL,
MERRUT, U. P.
15th February, 1925.

VACCINATION IN RURAL AREAS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The immortal story of the introduction of vaccination by Jenner is well known. "It is on record," writes Dr. C. Banks in a pamphlet on the subject, "that an English farmer named Benjamin Jesty intentionally inoculated his wife and two sons from a cow suffering from the disease as a protection from small-pox,"—probably the first instance in which such protection was resorted to. Yet the Indian farmer and rural cultivator has not appreciated the benefits of vaccination, and the annual victims of small-pox can be counted by thousands among men, women and children in this country.

Is there no way in which to break this wall of prejudice and opposition? These people are illiterate; scientific lectures do not interest them, and ordinary propaganda leaves them untouched. But if entertainment can only be combined with such teaching, much might be accomplished. I would suggest coloured lantern slides as an aid to popularising vaccination. If vaccinators were but trained in methods of popular lecturing and given the necessary outfit for popular lectures with coloured slides, vaccination might be popularised.

Some years ago, when serving in the vaccination department in Bengal, I saw many vaccinators carry out the operation in an entirely unprofessional and often septic manner. The results of such vaccinations are to render the method of protection unpopular. The vaccination staff should be trained, not only in the aseptic technique of the operation, but in methods of teaching and popularising vaccination. Only in some such way can improvement come about.—Yours, etc.,

S. P. NAG, L.M.S.

GOZINA, DASPUR, HOOGHLY,
22nd March, 1925.

TUBERCULOSIS SANATORIUM REPORTS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I remember to have read somewhere that in Germany the annual reports of all Sanatoria for tuberculosis are collected and edited in one booklet for the benefit of general practitioners. The scourge of tuberculosis is increasing in India, though there are but few Sanatoria for the treatment of tuberculosis in India. If the physicians in charge of these would only issue detailed annual reports with special reference to the treatment and results, I think it would not be difficult to collect all the information on advances in treatment for the enlightenment of the medical profession. If your staff would undertake such work in this country, it would materially help the mutual exchange of knowledge. I for one, as interested in the subject, am prepared to give my quota of help however humble. I am confident that the physicians in charge of different Sanatoria will gladly co-operate in such a work and give us the full benefit of their experiences.—Yours, etc.,

D. M. VASAVADA,
Assistant Surgeon.

BIKANER,
15th March, 1925.

[Note.—We would very gladly review such annual reports of tuberculosis Sanatoria in India, if received. At present the only one received regularly is that of the Union Mission Tuberculosis Sanatorium at Arogyavaram, S. India. The subject is of extreme importance in tropical medicine; but, unless we receive such reports regularly, we regret our inability to review them.

In this connection, we would like to point out that we have lately ceased to receive the annual reports of several Directors of Public Health, Surgeons-General and Inspectors-General of Civil Hospitals in different Provinces in India. The idea underlying such curtailment is—apparently—economy in stationery and postage. We profoundly deplore such a decision. The *Indian Medical Gazette* has at present a monthly circulation of over 3,000 copies in India, in addition to some 350 copies per month overseas. If such Provincial Governments neglect this source of publicity, they have only themselves to blame. The congestion in our available space has now been relieved, and reviews of the general public health activities in India are of first importance both to ourselves and to our readers. We would appeal to the many different officials concerned to help us in this matter.—EDITOR, I. M. G.]

CORIANDER SEEDS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In Birdwood's "Practical Bazar Medicines," on p. 47 of the 1920 edition, one reads that coriander (*dhania*) seeds are aromatic, carminative, and anti-spasmodic.

Having devoured with avidity the contents of this useful book, I have for the last four years been extensively using these cheap and equally effective Indian remedies with happy results. They make a special appeal to Indians, not merely because they are cheap, but also because they are essentially Indian.

I would like to know if any of your readers or contributors have found coriander markedly emmenagogue and diaphoretic in action. It has been my experience in three cases to observe a decidedly emmenagogue effect, not one of coincidence in any of the three cases. At the outset of a "cold" there is nothing so gratifying in its results as what I term coriander tea. I use one ounce of the crushed seeds, boiled in a breakfast cup of water to half the volume, add hot milk and sugar to taste and drink it hot before retiring at bed time.—Yours, etc.,

B. J. BOUCHE, I.M.D.,
Assistant Surgeon.

JUDOGH, SIMLA HILLS,
18th March, 1925.

A METHOD OF REDUCING DISLOCATIONS OF THE SHOULDER JOINT.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I describe below a method of reducing dislocation of the shoulder which I have been practising for the last 15 years. I have thus treated about 50 cases without a failure, and I think it can now be said to be a sound and very useful method. It is as follows:—

- (1) Make the patient stand in front of you, when you are also standing facing him.
 - (2) Raise the injured arm gently and place the forearm on your own shoulder in front; thus if the right shoulder is injured, you put the right forearm of the patient on your left shoulder and *vice versa*.
 - (3) Tell the patient to pass his sound hand below your other armpit and grasp the wrist of his injured arm firmly behind you. He thus encircles you in his arms.
 - (4) Put your thumb in his injured armpit, over the displaced head of the bone, and pass the fingers below and behind the shoulder so as to grasp it.
 - (5) Tell the patient to sit down. If for any reason he does not do so, press him down with your other hand.
 - (6) When he does so, the weight of his body acts as an extending force and the bone is found to leave its new place and then can be easily guided with your thumb to its proper place. It will go quietly and obediently very often of its own accord to its proper place.
 - (7) After reduction put the hand on the opposite shoulder and bandage as usual.
- From the above, it will be seen that the method:—
1. Is surpassingly simple, safe and satisfactory.
 2. No chloroform or any special appliance is required.
 3. Co-operation of the patient is secured from the beginning; therefore there is no struggling on either side.
 4. No injurious pressure is exercised over the axillary vessels and nerves as in some other methods.
 5. It can be practised on the spots. I reduced one on the sands of Back Bay, Bombay, while out for a walk in the evening.
- In fact it takes more time to describe the method than to actually demonstrate it.

It is fair to acknowledge what I owe to the gymnast and bone-setter of Kolhapur, whom I observed reducing a dislocation of one of his wrestling disciples, of course in his own way. I only improved upon it, and had to do so, not being so strong. He lifted the patient up from the ground by catching the elbow of the dislocated arm and guided the bone with his other hand. If the weight of the patient was not sufficient to dislodge the bone from its abnormal site, he asked some one to pull the patient's legs down. However crude it may look, the method always succeeded as stated by him. It also succeeds in my way.

I have taught and practically demonstrated this method to several young medical practitioners, who were then medical students at the B. J. Medical School, Poona, when I was there as a tutor and at the Medical School and Civil Hospital, Hyderabad, Sind, where I was the surgical registrar. I would be very glad to learn from them their experience of this method through your esteemed columns.—Yours, etc.,

S. C. SHRIKHANDE, M.C.P. & S.

SAUNDATTI DISPENSARY,
BELGAUM DISTRICT.

[Note.—Our correspondent does not state which variety of dislocation at the shoulder-joint he treats by this method. Presumably the sub-glenoid variety, one which is usually readily amenable to treatment.—EDITOR, I. M. G.]

Service Notes.

APPOINTMENTS AND TRANSFERS.

Lieutenant-Colonel R. W. Anthony, M.B., F.R.C.S.E., I.M.S., is appointed to officiate as Inspector-General of Civil Hospitals, Central Provinces, with effect from the 30th March 1925, *vice* the late Colonel J. A. Black, I.M.S., until further orders.

Lieutenant-Colonel J. R. J. Tyrell, I.M.S., Agency Surgeon in Bundelkhand, is appointed to officiate as Political Agent in Bundelkhand, in addition to his own duties, with effect from the 23rd March 1925, and until further orders.

The services of Lieutenant-Colonel J. W. D. Megaw, M.B., I.M.S., are placed permanently at the disposal of the Government of Bengal, with effect from the 15th November 1921.

The Viceroy and Governor-General has been pleased to make the following appointment on His Excellency's personal staff, with effect from the 18th March 1925.

To be Honorary Surgeon.

Lieutenant-Colonel G. Tate, M.B., I.M.S., *vice* Lieutenant-Colonel D. W. Sutherland, C.I.E., M.D., I.M.S., tenure expired.

The services of Major J. B. Hanafin, C.I.E., F.R.C.S.I., I.M.S., are placed temporarily at the disposal of the Government of Assam, with effect from the date on which he assumes charge of his civil duties.

The services of Captain P. D. Chopra, I.M.S., are placed temporarily at the disposal of the Government of the Punjab for employment in the Jail Department, with effect from the date on which he assumes charge of his duties in that Department.

The services of Captain G. H. Mahony, M.B., I.M.S., are placed temporarily at the disposal of the Government of Central Provinces, with effect from the date on which he assumes charge of his civil duties.

Captain K. R. K. Iyengar, D.P.H., M.B., I.M.S., an Officer of the Medical Research Department, is on Assistant Director of the Central Research Institute, Kasauli, with effect from the 9th March 1925.

LEAVE.

Lieutenant-Colonel S. Hunt, I.M.S., an Agency Surgeon, is granted leave on average pay for 6 months and 22 days combined with leave on half average pay for 1 year 6 months and 14 days under the Fundamental Rules, with effect from the 24th February 1925.

Lieutenant-Colonel F. P. Mackie, O.B.E., M.D., F.R.C.P., F.R.C.S., I.M.S., Director, Bombay Bacteriological Laboratory, is granted leave on average pay for 6 months, with effect from the 10th April 1925, or the subsequent date on which he may avail himself of it.

Lieutenant-Colonel W. F. Harvey, C.I.E., I.M.S., Director, Central Research Institute, Kasauli, is granted preparatory to retirement, leave on average pay for 8 months combined with leave on half average pay for 20 months, with effect from the 25th May 1925, or the subsequent date on which he may avail himself of it.

In modification of the orders already issued, Major W. D. H. Stevenson, C.I.E., I.M.S., Director, Pasteur Institute, Kasauli, is granted leave on average pay for 8 months combined with leave on half average pay for 4 months, with effect from the 3rd October 1924.

ADMISSION TO THE INDIAN MEDICAL SERVICE.

To be Captains.

W. Aitchison and R. W. H. Miller. Dated 1st January 1925.

Gilbert Johnston Smith. Dated 3rd March 1925.

To be Lieutenants.

Cuthbert Alfred Bozman, Alfred Bosenbloom, Martin Patrick Conroy, Walter Scott and Stanley Charles Harwood Worseldine. Dated 3rd March 1925.

PROMOTIONS.

Lieutenant-Colonels to be Colonels.

H. Boulton, C.B.E., I.M.S., *vice* Colonel F. Wall, C.M.G., K.H.S., I.M.S., retired, with effect from the 5th March 1925.

Colonel Boulton's tenure of appointment will reckon from the 10th March 1925.

Captains to be Majors.

J. C. De. M.B., I.M.S. Dated 26th January 1925.
S. S. Sokhey, M.B., A. Seddon, M.B. and R. V. Martin. Dated 26th January 1925.

Lieutenant to be Captain.

W. H. Critien, I.M.S. Dated 8th December 1924.

RETIREMENTS.

Lieutenant-Colonel O. St. John Moses, M.D., F.R.C.S.E., I.M.S. Dated 20th March 1925.

Lieutenant-Colonel R. A. Lloyd, D.S.O., M.D., I.M.S. Dated 13th January 1925.

Lieutenant-Colonel Sir D. G. R. S. Baker, Bt., I.M.S. Dated 14th February 1925.

Major J. H. Horne, I.M.S. Dated 11th February 1925.

MISCELLANEOUS.

The names of the undermentioned have been brought to notice for distinguished service during the Operations in Waziristan, 21st April 1923 to 31st March 1924, by His Excellency General Lord Rawlinson of Trent, G.C.B., G.C.S.I., G.C.V.O., K.C.M.G., Commander-in-Chief in India, in the Despatch dated the 11th June 1924 (Published in the Supplement to the *London Gazette*, dated the 18th November 1924).

Captain T. R. Birmani, I.M.S.

" C. M. Ganapathy, M.C., I.M.S.

" D. V. O'Malley, O.B.E., M.B., I.M.S.

" M. V. Pathak, I.M.S.

" P. Prasad, M.B., I.M.S.

" R. V. Rau, I.M.S.

The King has been graciously pleased to give orders for the following appointments to the Most Excellent Order of the British Empire, for valuable services

rendered in the field in connection with Military Operations in Waziristan, 21st April 1923 to 31st March 1924:—

To be Members of the Military Division of the said Most Excellent Order:—

Captain A. N. Bose, I.M.S.

" H. H. Elliot, M.C., I.M.S.

NOTES.

BOVRIL, LIMITED.

PRESIDING at the twenty-eighth-annual general meeting of Bovril, Limited, held in London on 4th March, Sir George Lawson Johnston (chairman) congratulated the shareholders on having had a successful year. He said:—

"The gross profit on trading, less advertisements, stands at £639,123, as against £571,491 for the year 1923. This gross profit, constitutes a record."

Referring to recent advertising schemes, Sir George Lawson Johnston emphasised how the display of some of the series of Bovril posters brought back advertising memories of the last quarter of a century, and many were surprised to see how long a slight tinge of humour had been a feature of these posters, which otherwise depict a serious food fact.

It is rather surprising that it is only in recent years that a touch of humour in posters has become prevalent.

Sir James Crichton-Browne said the Company was constantly receiving testimony to the value of Bovril from all quarters of the globe and under the most diverse conditions. Bovril had been used largely by the enterprising Oxford University Arctic Expedition, by which, for the first time in history, an aeroplane had been employed in Arctic exploration; it had been carried by Mr. Simpson, of the *Daily Telegraph* Expedition, which twice crossed the continent of Australia in a Bean motor-car; and supplies of Bovril had been laid down at ten selected depot points for the use of the great Cape to Cairo motor expedition, now in progress under the leadership of Captain Court Treatt. These were emergency uses of Bovril. The extent of its routine and habitual consumption was best shown by the figures which had been submitted to the shareholders. Bovril was of firmly established reputation and world-wide acceptance, and he ventured to predict for it a still growing popularity. It represented in an agreeable and easily assimilable form that animal protein upon which all the great nations of the world had been built up, and the amount of which, as a food constituent—might be taken as a measure of the physical efficiency and power of resistance to disease of the different races of India.

OPHTHALMOLOGICAL CONVENTION,
LONDON, 1925.

THE Ophthalmological Society of the United Kingdom, together with its affiliated Societies, has decided to hold in London from July 14th to 17th, 1925, a Convention of English-speaking Ophthalmological Societies and Associations, all members of which are invited to attend. On Monday evening, July 13th, a reception will be held at the Royal College of Surgeons of England. Four mornings, two afternoons and one evening will be devoted to the scientific work of the Convention. The Bowman lecture will be given by Sir John Parsons, C.B.E., F.R.S., on the afternoon of July the 16th. On the evening of July 15th there will be a discussion on "The Evolution of Binocular Vision," in which Sir Charles Sherrington, Sir Arthur Keith, Sir Frederick Mott, Prof. Elliot Smith and Prof. S. E. Whitnall will take part. "Microscopy of the Living

Eye" will be discussed by Dr. Gordon Byers, Dr. A. J. Bedell, Mr. Harrison Butler, and Mr. Basil Graves. A garden party will be given by Sir William and Lady Lister; there will be a reception at the Wellcome Medical Museum; and excursions to Oxford and to Cambridge. The registration fee for those who are not members of the Ophthalmological Society of the United Kingdom will be £2. Mr. Leslie Paton, 29, Harley Street, London, W. 1, is Secretary to the Convention, and those intending to attend the Convention should communicate with him.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE. DIVISION OF TROPICAL MEDICINE AND HYGIENE.

The following Medical Officers passed the School Examination at the termination of the 77th Session (January-March, 1925):—

Passed with Distinction.

Craighead, A. C., Winner of "Duncan" Medal.
Haworth, A. N.
Klaber, R.
Goldsworthy, N. E.
Mohammed, A. S.

Passed.

Lumsden, K.
Vickers, W. J.
Garnham, P. C. C.
Campbell, A. H.
Cook, E. N.
Banks, J. N.
Graham, J. W.
Monks, A. B.
Fraser, E. M.
Struthers, E. B.
Grant, P. F. A.
Brown, H. H.
Bowyer, J. H.
Ali, M.
Gordon, J.
Manley, J.

Passed.

Stuart, J. L.
Mumford, R. H.
Pan, T. C.
Chan, V. F. T.

EXAMINATION RESULTS. FACULTY OF TROPICAL MEDICINE, BENGAL. SESSION 1924-1925.

At the examination in April 1925 for the Diploma in Tropical Medicine (Bengal), held at the Calcutta School of Tropical Medicine, 29 candidates appeared. Of these, the following 21 passed:—

Passed with Distinction.

1. Dr. T. K. Raman, M.B., B.S.

Passed (not in order of merit).

1. Dr. Abdul Majed, M.B.
2. " Banta Singh, M.B., B.S.
3. " N. H. Bharucha, L.M. & S.
4. " C. J. D. Burghall, I.M.D.
5. " Ram Kinkar Chakravorty, M.B., D.P.H.
6. " Probbhat Chandra Das, M.B.
7. " Nripes Chandra Das Gupta, M.B.
8. " Kshirode Lal De, M.B.
9. " R. S. Donaldson, M.B., Ch.B. (Glasgow).
10. " Jotindranath Dutt, M.B.
11. Miss A. G. Gault, M.B., B.S.
12. Dr. Nagendra Nath Ghosh, L.M.P.
13. " Umapati Gupta, M.B.
14. " R. V. Kalyanpurkar, M.B., B.S.
15. " Rajani Mohan Kar.
16. Capt. W. E. Mascarenhas, M.B., B.S.
17. Dr. C. McGuire, I.M.D.
18. " S. Nagaswami, M.B., B.S.
19. Lt. H. Vasant Rao.
20. Capt. Bijayananda Sen Gupta, M.B.

"ETHIDOL" ETHYL IODO-RICINOLEATE.

"Ethidol" is a preparation evolved in the laboratories of Messrs. Burroughs Wellcome Co. as an outcome of the successful internal use of "Iodidin," a calcium salt of iodo-ricinoleic acid. In "Ethidol" the calcium base is replaced by the ethyl radical and the result is a product, presenting 20 per cent. of iodine in organic combination, suitable for intra-glandular injection or inunction.

Its therapeutic application is naturally based upon its high iodine content and penetrative power, and, after clinical trials extending over two years, sufficient evidence has accumulated to indicate its usefulness and to justify its general introduction to the medical profession.

As an injection it has been employed in epilepsy, rheumatoid arthritis and in the treatment of tuberculous and scrofulous glands.

As an inunction successful clinical results have followed its use in simple goitre and rheumatoid arthritis and, in view of its iodine content, its further trial is suggested in sprains, neuritis and some skin affections such as eczema, psoriasis, ringworm and erysipelas. "Ethidol" does not stain or cause local irritation.

It may be heated to 100° C. for sterilisation before injection. Injections are stated not to cause induration and are usually painless.

Should reduction in strength be considered desirable, it is miscible with almond oil, olive oil, "Paroleine" or "Borofax."

'Ethidol' is issued in bottles of 1 oz. and 4 oz.

MARGOSIC PREPARATIONS.

We have received from the Calcutta Chemical Co. 35-1, Panditia Road, Ballygunge, Calcutta, a small brochure dealing with their margosic preparations. The antiseptic and stimulating properties of "neem" leaves have been recognised in India for centuries. As shewn by Dr. K. K. Chatterji, F.R.C.S., Dr. C. R. Roy, Mr. R. N. Sen, M.A., M.Sc., and others, the active principle is a fatty acid, margosa oil, which is stated to have bactericidal and anti-protozoal properties, which are further enhanced on combination with different metals. The ethyl esters of the oil have a higher percentage of the fatty acid and are therapeutically more active than the oil itself.

Of the many preparations listed, "Margampules" are suitable for intramuscular—or, with due care, for intravenous-injection; "Margoloids" are suitable for oral use, and "Margolene" for inunction. Dusting powders, soaps, and a dental powder are also prepared. These preparations are advocated in skin diseases in general, for injection and inunction in cases of syphilis, in leprosy, sepsis in general, tubercular ulcers and sinuses; and for urethral irrigations of "Silvmarg"—a silver compound—in gonorrhœa. Those interested in the development of indigenous Indian drugs might do well to turn their attention to these interesting preparations.

'SOLOID' BENEDICT TEST.

BURROUGHS, WELLCOME & Co. have issued a 'Soloid' preparation of the Benedict qualitative test for glucose in urine. The presence of sugar is indicated by change of colour and by the formation of a yellowish red precipitate.

This test is remarkably easy to carry out and is characterised by simple reading. It is reputed to be considerably more delicate than Fehling's test. For example, urine containing 0.1 per cent. of glucose produces a change of colour, whilst this change is very decided when 0.2 per cent. or more of glucose is present.

In many bio-chemical laboratories, particularly in America, the Benedict test has replaced other methods. In view of the large and increasing number of diabetics who are being treated with Insulin and who

are being taught, as part of the routine insulin treatment, to examine their urine daily, this 'Soloid' preparation will be appreciated by medical men. Its keeping qualities and the fact that it obviates the necessity of measuring out stock solutions will readily be appreciated.

Two methods of procedure are given, one of which is most convenient for use in the ordinary household and which gives a clearly defined reading for amounts as low as 0.1 per cent.

'Soloid' brand Benedict Test is not only more delicate than the older methods, but is specially suitable for qualitative analysis outside the laboratory, especially for patients to whom insulin is being administered and whose urine sugar-content must remain the deciding indicator in treatment.

'Soloid' Benedict Test is supplied in cartons containing material for 24 tests.

WATSON'S "MICROSCOPE RECORD."

SOME time ago we commented upon the enterprise of Messrs. W. Watson & Sons, Ltd., 313, High Holborn, London, W. C. 1, in issuing gratis a journal devoted to the interests of microscopy. No. 4 issue—for January, 1925—of "Watson's Microscope Record" is as interesting as its predecessors. In the current microscopy column the question of the sub-stage condenser is discussed; Mr. J. M. Offord, F.R.M.S., discusses the microscope and pond life; Mr. H. Wrighton, B.Met., describes new photo-micrography apparatus; whilst in article entitled "Why not Micro-fungi?" draws attention to the extreme interest and simplicity of methods for the study of this interesting group of organisms. Mr. G. H. Needham describes a new method for the preparation of styrax and balsam of Tolu for use as mounting media of high refractive index;—a method especially suitable for the study of diatoms, but also useful for such objects as helminthic ova and coccidial oocysts. The notes and queries column deals with the photography of lightly stained specimens, opaque mounting, condensers and thick slips, and colour filters. The whole number is one which will appeal both to the general microscopist and to laboratory workers in general.

THE M.H.S. CLIP.

MESSRS. BRIDGE & Co., 92, Chancery Lane, London, W. C., have forwarded to us samples of a very ingenious card index clip, designed by Mr. J. M. F. Whitby, a medical student in his final year, intended for fastening together index cards, medical history sheets, etc. Circular pieces of transparent linen, 0.7 inches in diameter, are sewn together across one diameter so as to make a little book of four semi-circular leaves. Two pairs of adjacent surfaces are covered with adhesive for the purpose of holding the edges of cards placed between them. The hinges are practically untearable. Cards can thus be bound together into a book with these adhesive hinges; and additional cards be added to make the book of any thickness. The cards fold flat against each other when thus fastened, whilst the transparency of the fastener is an additional advantage. The price is 1s. 3d. per 100, or 5s. 9d. per 500 clips, plus postage.

ANTIPHLOGISTINE AND ITS IMITATIONS.

We have received the following note from the Denver Chemical Manufacturing Co., which we publish with pleasure:—

"From time to time unscrupulous manufacturers exploit imitations of Antiphlogistine under misleading and confusing names. These preparations, purporting to resemble as nearly as possible the original Antiphlo-

gistine, are often without hygroscopic or osmotic properties, and are usually inert.

"A package of one of these nicknamed imitations sent to The Denver Chemical Manufacturing Company, when analyzed at their laboratory in New York, was found to be a grimy mixture of clay and crude oil, which burned with the characteristic offensive crude oil flame and stench. The preparation was not only without therapeutic value, but the application of such material in some conditions would work certain harm.

"A large percentage of Antiphlogistine is chemically pure glycerine, which, as we know, has a strong affinity for water. The glycerine exposed to the air will absorb much moisture and this reduces its hygroscopic power. The formula for Antiphlogistine has long been in the hands of the medical profession and thus they know always what they are prescribing. It is more the process of manufacture that counts. The Denver Chemical Manufacturing Company are specialists, having devoted over a third of a century to the manufacture of this one product, and the thought and energy of its entire personnel have been with but one thought in mind—Antiphlogistine.

"Chemicals of this kind which are carelessly handled and not properly compounded lose whatever therapeutic value they may have before they ever come into the hands of the consumer.

"Since Antiphlogistine is a strictly ethical product, it is impossible for the manufacturers to caution patients directly against these spurious preparations. They must depend upon the physician who prescribes for the patient and upon the druggist in whose hands the patient trusts his prescription. More than 200 imitations purporting to be the same as Antiphlogistine have been exploited in different parts of the world during the past few years, but in almost every instance, they have utterly failed to impress the doctor, the reason being that products of this kind fail in at least one important particular—that is, they do not have the hygroscopic, osmotic property upon which the success of Antiphlogistine so greatly depends."

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints of the literary pages of the "Gazette" gratis, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, MESSRS. THACKER, SPINK & CO., P. O. Box 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to the *Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of the *Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

CHOLERA IN BENGAL: PAST AND PRESENT.

By A. B. FRY, C.I.E., D.S.O., M.D. (Lond.), D.P.H.,
LIEUTENANT-COLONEL, I.M.S.,

*Professor of Hygiene, Calcutta School of Tropical
Medicine and Hygiene.*

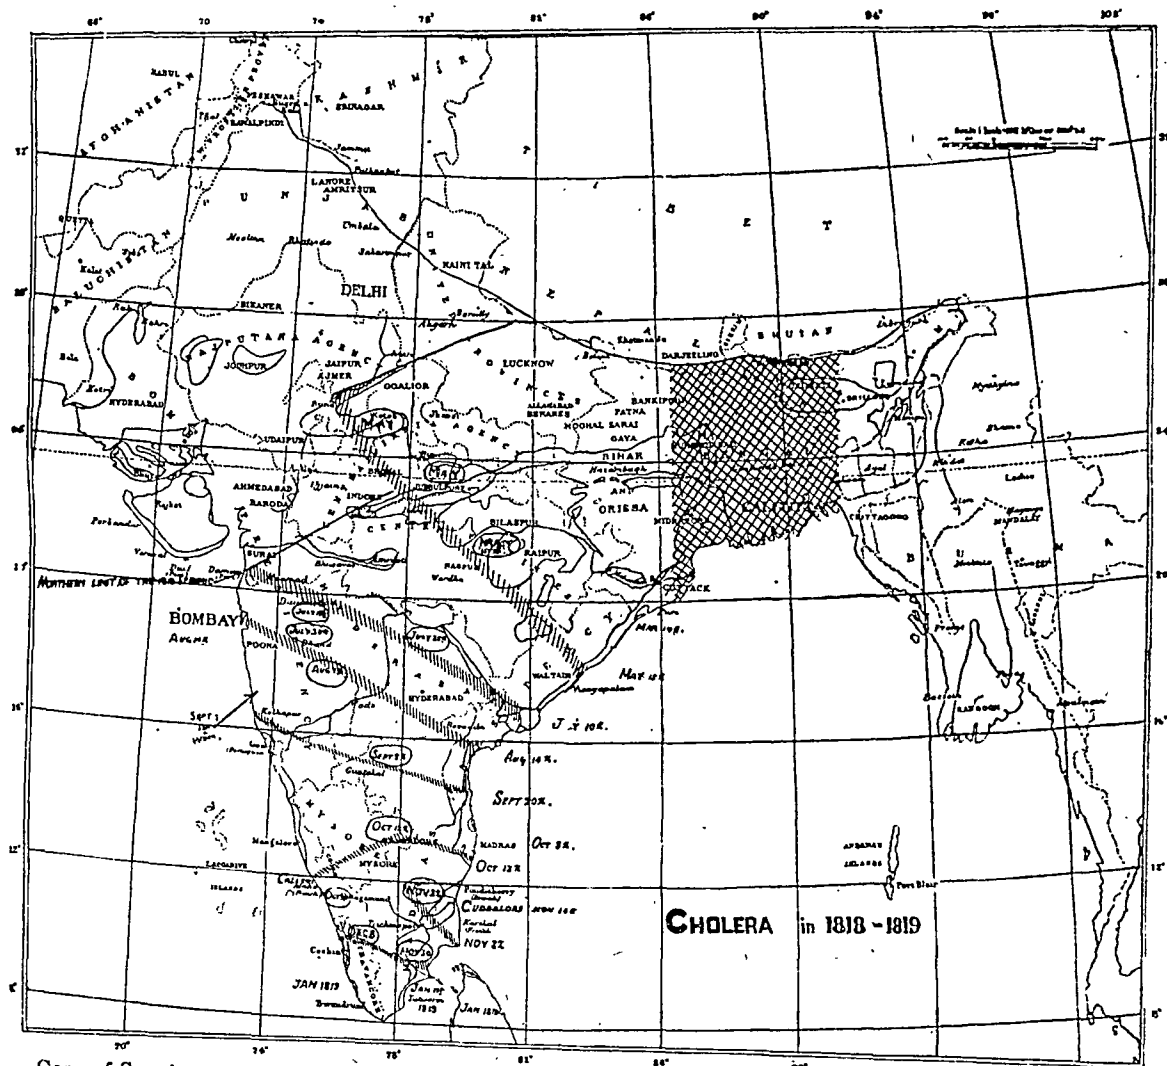

At the October session of the Standing Committee of the Office Internationale d'Hygiene Publique, I was asked the following questions:—

(1) Is Bengal nowadays the endemic home of cholera, as it used to be in the past?

available. (1) Hirsch's Handbook of Geographical and Historical Pathology," 1883, Vol. I; (2) Macpherson's "Annals of Cholera," London: 1872; (3) "Report on Epidemic Cholera Morbus in the Presidency of Bengal in 1817 to 1819" by James Jameson, Calcutta: 1820; (4) "Report on Epidemic Cholera in Madras" by W. Scott, 1824; (5) "Report on Cholera Epidemics from 1817 to 1872" by James L. Bryden, Calcutta: 1874; (6) The Annual Reports of the Sanitary Commissioner with the Government of India; and (7) "A Treatise on Asiatic Cholera" by C. Macnamara.

Hirsch says: "In the year 1817 there began the epidemic extension over India of a disease which

MAP I.

Copy of Scott's map showing the progress of epidemic cholera in 1818 and 1819. The portion cross-shaded is that always shown in old reports of the Sanitary Commissioner with the Government of India as the home of endemic cholera from which all epidemics start.

(2) Does Bengal still spread epidemic cholera throughout India and thence to the rest of the globe?

This article is an attempt to answer this serious indictment.

Past History of the Disease.

Concerning the cholera of the last century there is a considerable amount of literature

had previously been known as an endemic in a few districts of the country. In that and the following years it overran the peninsula and crossing the borders of its native territory it penetrated to almost every part of the habitable globe." He goes on to give a full history of four great pandemics 1817-1823, 1826-1837, 1846-1849 (which remained so late as 1854 in the islands of the West Indies), and 1865-1875 (a pandemic

which was noticeable for the rapidity with which it spread to Europe and the Western Hemisphere). This last epidemic commenced in the lower Ganges basin in 1863 and leaving India in 1865 was widely spread in North and South America in 1866, reaching Guadeloupe directly by ship from Marseilles, and to Halifax in Nova Scotia by ship from Liverpool.

Scott traces the spread of the 1817 epidemic from Bengal through the peninsula to Ceylon which was reached in January 1819. Map I is a copy of the map which illustrates his report.

its natural territory in lower Bengal, by what Bryden terms 'the epidemic highway,' across the Central Provinces, and southward through the Deccan and Bombay Presidencies towards Madras territory, which in a longer or shorter space of time is occupied. Nor does cholera terminate with the extreme southern limit of the peninsula. In all true epidemic invasions, from 1818 down to 1870, it has been carried on to the neighbouring island of Ceylon. In this southern progress of cholera a period of two years may elapse (as in the latest invasion) before the epidemic has

MAP II.

Cunningham in the annual report of the Sanitary Commissioner with the Government of India quotes Scott's narrative as follows:—

"The history of the epidemic advance of cholera in 1818, as detailed in Scott's narrative, is, in point of fact, the history for all time of the mode in which the Peninsula and Southern India are invaded. In every new invasion there are sure to be some minor differences as to the rapidity of movement of, and the extent of country covered by cholera, but the main facts are unalterable. The broad truth in regard to invasion to be borne in view is that the great body of cholera which invades Southern India leaves

travelled its southern course from Bengal to Ceylon, or, as in 1818, the whole journey may be completed in six or seven months. The epidemic of cholera that left Bengal in the spring of 1818 reached Ceylon in January 1819; but, with all the facilities for rapid communication introduced during the last half century, we find that the great body of moving cholera in the last epidemic invasion which fell upon the Central Provinces in the spring of 1868, did not reach Ceylon until May 1870."

Jameson's history of the 1817-1820 epidemic is quoted by Bryden. "There was universal cholera in the endemic province in the first six

months of the year 1817. In May and June it occurred to an unusual degree in Nuddea and other districts. It did not attract notice until August when the rapidity of its progress and general extension caused great alarm.

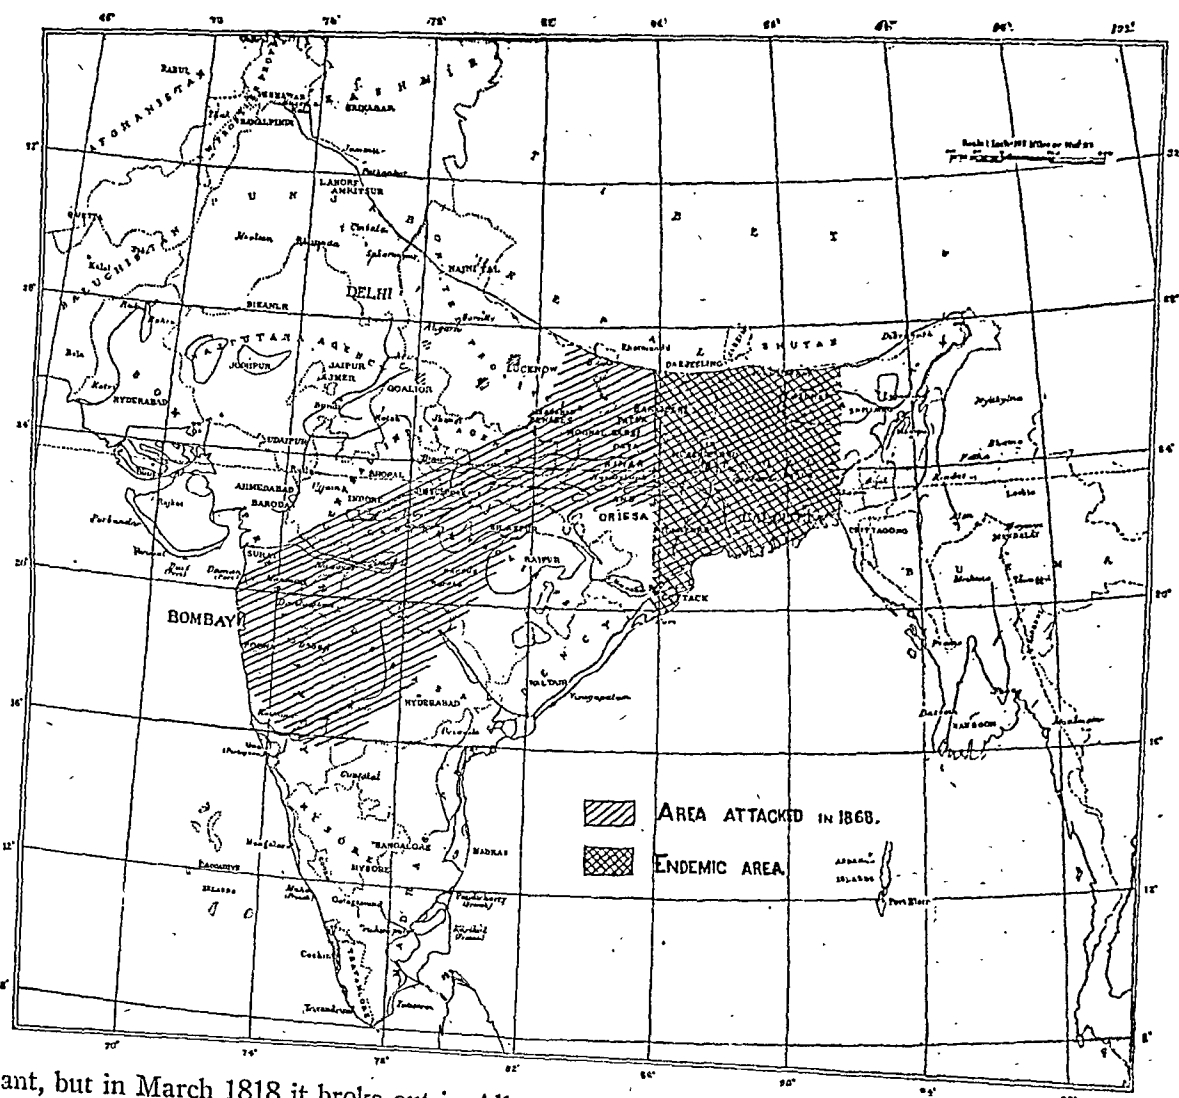

"Facts prove that cholera broke out at remote places at one and the same time. A month before Jessore was attacked the disease was epidemic in Bihar and Dacca. In August it raged in Chittagong. In the autumn of 1817 cholera was epidemic from Sylhet in the east to Cuttack and Puri and extended west nearly to Allahabad.

"In the winter of 1817-1818 cholera remained

outbreaks 1855-1858 and 1859-1862 with this epidemic of 1817-1820 described by Jameson is perfect."

Bryden, Cunningham and other writers regard the 1817-1820 epidemic as the starting point of endemic cholera in Bengal. The disease was known in India before then. In the Nidán of Susruta a disease called *Vishuka* is described which is typical of acute cholera. Hippocrates, Galen and Celsus are witnesses to the existence of cholera. The dark ages are barren of records but Gaspar Correa, a Portuguese physician, in "Lendas da India" (1503) records that 20,000

MAP III.

dormant, but in March 1818 it broke out in Allahabad and reached Lucknow in April and May. In fact, it advanced steadily west on a front of 300 miles. It then took a south-west direction to almost every town and village of Bundelkhand and Saugur, thence this southerly stream headed to Bombay. The northern branch passed from Oudh to Agra and Delhi in August 1818. There was a northerly extension to Nepal. In 1821 the disease reached the Persian Gulf, Syria and Asia Minor and in 1823 appeared on the Caspian and Mediterranean coasts."

Bryden remarks on this:—"The parallel of the

men of the army of the king of Calicut died of "a disease sudden-like which struck with pain in the belly so that a man did not last out eight hours." He reports further that there was an epidemic in Goa in 1543 which was known as *moryxy* and by the Arabs as *hachaiza* (haiza). It must be remembered that at this time no Europeans knew anything of the Indian continent, and the disease may well have had a widespread existence. In 1774, Dr. Paisley, writing in Madras, says: "This dangerous disease *cholera morbus* is the same we had in Tricomalee." In 1770 it was endemic in Arcot and Travancore,

and in April 1783 it was supposed to have killed 20,000 in Hardwar (Macnamara).

Bryden, who was the statistical officer with the Sanitary Commissioner, published his voluminous report in 1874 and gives a clear description of repeated instances where cholera spread from what he terms its "epidemic home" in Lower Bengal across India by two main routes described by him as the northern epidemic highway up the Ganges valley to Afghanistan and Persia, and the southern epidemic highway across the Central Provinces to Bombay, Madras and Ceylon.

In no single year during the period 1817-1872 did cholera spread in the reverse direction and in no single year was Bengal free from the disease. I attach two maps (Maps II and III) copied from many published by Bryden, showing the east to west spread. In these two maps I have cross-shaded the area always coloured in old reports as the area of endemic cholera.

The Civil Surgeon of Lahore writes in 1879 (*vide* Report of the Sanitary Commissioner, 1879):—

"The experience of many epidemics has satisfied me that cholera never arises spontaneously in Lahore. In all the epidemics which I have known it has travelled up-country and has been regularly traced along the Grand Trunk Road or railway. Hence, in the present day when cholera is heard of at Umbala or Phillour, we know pretty certainly that sooner or later during the same season it will reach Lahore. In former years it was often some weeks in travelling from Umbala to this place, but now that the railway is open, it comes within a few days."

The Sanitary Commissioner remarks "there has never been recorded an epidemic travelling to Lahore from Multan on the south-west or from Peshawar on the north-west."

Cholera of past 50 years.

There can be no doubt as to the part played by India in originating the great pandemics of the past nor of the fact that Bengal was the starting point in India itself. How far is that still the case?

A study of the cholera mortality statistics from 1899 onwards which are published in annual reports of the Public Health Commissioner with the Government of India show plainly that there is little change in the situation.

I have put the figures into Graph No. 1, illustrating separately the mortality of Bengal, United Provinces, Central Provinces and Bombay.

The Bengal curve shews that no single year of the period under review has shown a mortality of less than 40,000 persons in Bengal. The years 1892, 1900 and 1908 are notable epidemic years, and there are many years of smaller epidemics. The curve also shows the wide variation from year to year, and it is noteworthy that there appears to be no tendency for the mortality of one year to influence that of the next. The worst

epidemic year, 1900, was preceded and followed by years of comparative health. An examination of the United Provinces curve shows that there is a definite correlation with that of Bengal.

The year 1900, which was a famine year, is particularly interesting as the United Provinces is not so much influenced as Bombay, and this epidemic seems to have followed what Cunningham and Bryden in the old reports called the "southern epidemic highway" through the Central Provinces to the west coast of India. In the years 1892 and 1894 the northern epidemic highway through the Ganges valley was followed.

It would seem that during the past 50 years a high cholera mortality in Bengal coincides with a

Graph No. 1

CHOLERA MORTALITY CHART FOR 30 YEARS BY PROVINCES

Bengal
U. Provinces
Bombay
Central Province

high cholera mortality in other parts of India in the same year. There appears to be no record of any province suffering a bad epidemic in a year when Bengal cholera was moderate. Can we avoid the inference that Bengal is the culprit? If it is, the district cholera mortality returns should show repeated movements of epidemics from East to West. In the days before railways such epidemic movements were easy to trace. Bryden reports how epidemics left Bengal and infected a near-by area; this area became a seat of epidemic next year and spread forward north-west and south with great regularity. Now the movement is more rapid. The report of the Sanitary Commissioner for India (1900) says that in the later months of 1899 and in the early

months of 1900 cholera was severe in Bengal and Assam, but that in April that year epidemic cholera broke out in widespread fashion, appearing in the Khyber and at Cabul in June, and in Kashmere in August. The epidemic was at its highest by June in the United Provinces, and in July in the Punjab. The quick jump to the Khyber and Cabul is reasonably explained by the rapidity of railway travel and we know of the considerable efflux of Cabuli traders from Calcutta in the spring. Increased facilities for trade and the fondness which Indians have cultivated for railways and movement have altered the situation, and it cannot be shown that cholera sweeps steadily west from Bengal, and it is doubtful whether other parts of India are not establishing endemic centres of their own. The much bigger attendance at religious festivals—so well known for their influence in spreading cholera—and the dispersal of infection in all directions from these must in many cases reverse the direction of flow.

The endemic area.

Graph No. 2 shows the seasonal prevalence of cholera in the various divisions of Bengal. Seasonal prevalence is very constant.

Graph No. 2

Monthly mortality curve for combined 21 years
1900 - 1920.

The most easterly parts of the province are the Chittagong and Dacca divisions. Here the months of maximum mortality are the two dry, cold, winter months of December and January. There is a secondary peak in April.

The curve of the Presidency division follows the Dacca curve very closely.

The curve of the Patna division shows a complete reversal of seasonal prevalence. There is only one peak, and that is in the monsoon months of August and September. In the four cold weather months there is no cholera. This conforms to the seasonal incidence of the United Provinces.

The curve of the Rajshahi division which is that part of Bengal Proper north of the Ganges conforms fairly well to the curve of South-East Bengal.

It is in the Bhagulpur division, between Rajshahi and Patna, that the change of seasonal incidence takes place. The curve for the whole division shows a transition stage, and when one comes to statistics of individual districts the change appears between the Purnea and Bhagulpur districts. The Purnea district is liable to severe spring cholera, and in Bhagulpur and further west the summer rainy season is the worst cholera time.

This line is precisely that marked by the earlier writers as the western limit of the endemic area.

It is noticeable that in this division not only does the seasonal incidence change, but the endemic cholera of Eastern Bengal changes to epidemic. In 1900 there was a violent April epidemic in Purnea followed by a less explosive but none the less severe epidemic in Bhagulpur which lasted through the summer. In all, some 60,000 fatal cases occurred. The next year there were only 862 deaths in the two districts combined. Such a wide variation from year to year is not found in Bengal proper.

It is not easy to trace by statistics movements of cholera month by month from east to west. It can be done some years from one district to the next and even from one division to another, but I have not been able to get correlation tables except by selection. Still we have enough evidence to show that the Bengal delta is still the home of endemic cholera and this still spills over to the western districts.

The present day.

The latest monthly epidemiological report of the Health Committee of the League of Nations states that Java, the Malay States, Indo-China, the Philippines and Siam, all countries where cholera might reasonably find an endemic home, have a few sporadic cases only, and the rest of the habitable globe is free. Yet India is reporting many thousands of deaths each month. Why is it that cholera should attack these countries and fail to establish endemicity, whilst Bengal has been highly endemic without a break for over 100 years? Why should Bengal be the endemic home and not Madras or Bombay?

We know that the cause of cholera is the vibrio of Koch. We know that it is a delicate organism which can withstand cold but not heat, desiccation or sunlight. Greig's experimental work

proved that rice-water stools containing as they do a pure culture of the cholera vibrio, even if kept in the dark, become sterile in four days. How then does infection persist through the rains in Eastern Bengal? Graph 2 shows the cholera mortality curve typical of Eastern Bengal districts. From June to October very few cholera deaths are reported. These are the rainy months when Eastern Bengal is mostly under water except for the raised villages. Yet year after year as soon as the land dries up cholera re-appears in mild epidemic form. If there have been tornados and tidal waves bringing salt water into the rivers and tanks, then as in 1876 and 1897 the cholera assumes fulminant epidemic proportions. After the devastating cyclone of 1897 the Chittagong district suffered 21,000 deaths from cholera in the following 12 months. These Eastern Bengal districts where cholera is so persistent have a heavy rainfall. December and January are the only dry months. They are fertile and support in comfort a population of 800 to the square mile. This density of population must be a factor.

An account of the Faridpur district is found in a book by the late Major J. C. Jack, I.C.S., entitled "The Economic Life of a Bengal District." He gives the following figures illustrating economic conditions:—

Classified as living	Families.
In comfort ..	167,139
Below comfort ..	96,294
Above indigence ..	63,969
In indigence ..	14,706
Total	342,108

Though a certain number of families are described as living in indigence, yet these by dint of menial subsidiary employment are far removed from starving point, and famine,—that great associate of epidemic cholera,—does not occur in these Eastern Bengal districts.

Drinking water supplies.

The Eastern Bengal districts are entirely agricultural; towns hardly exist and the villages are more groups of hamlets than close-packed villages as in Upper India. The land is the latest part of the delta formed, and is flooded in the rainy season. The villages or hamlets, therefore, are all built on artificial mounds. Major Jack writes:—"The south-west part of the Faridpur district is a vast marsh, yet in the last century population has flocked to this basin to such purpose that this dismal swamp now contains 800 people to the square mile. For 8 months of the year the country is a lake 700 square miles in extent, whose surface is broken only by the village clumps and by the narrow strips of land which mark the course of the streams; in the other four months large parts dry up and enable crops to be grown or gathered. When a village is first founded a tank is dug and the earth from it heaped up until banks are raised above flood level." This tank serves all domestic uses,—bathing,

cooking, and washing clothes, as well as drinking water. In some of the better class hamlets a second pond is reserved for drinking water supplies.

With such a water supply it is easy to understand how an epidemic can spread. It is less easy to explain why endemic cholera persists.

Can it be a matter of chronic carriers and a community with a high degree of acquired immunity sensitized by the onset of the cold season which lowers their none too abundant vitality? The existence of the carrier has been proved by Greig and others, but the existence of the chronic carrier analogous to the enteric carrier is denied by some. Greig has proved that the mucous membrane of the gall-bladder is sometimes severely affected, and I have personally isolated a vibrio—indistinguishable from the cholera vibrio—from a man suffering from recurrent colic, from whom no history of a cholera attack could be elicited.

To theorise is fatally easy. To establish a theory such as I have enunciated would need a prolonged spell of field work in the endemic area, examining alvine discharges of great numbers. It might be that during the off season, from May to October, the vibrio is attenuated by conditions of temperature and humidity and becomes a normal inhabitant of the bowel of immune persons. This is again theory, but we do know that many persons are infected without suffering with the disease. Greig showed that 6 out of 27 contacts at Puri were excreting vibrios. The Japanese Port Authorities at Moje examined 120,000 immigrants and detected by bacteriological methods 8 cholera cases and 11 carriers.

Hirsch quotes the mortality of epidemic cholera in East Africa and shows that the mortality was affected by race:—

6.5 per cent. of the total Hindi population died.

10 per cent. of the total Arab population died.

25 per cent. of the total Negro population died.

It is not unreasonable to suppose that racial and acquired immunity may be responsible for a large number of chronic carriers or ambulatory cases.

Given a starting point in these eastern districts and an explanation of the "carry over" season it is not difficult to see how cholera gets a good send-off each cold weather. The dry season is the season of movement. Jack states that "during the dismal period of the rains water is everywhere and all men go afishing and lead an idle life. From December to February all are engaged in cutting the winter rice crop, and there is much emigration and immigration of hired labourers who are hired, lodged and fed for a week or more."

This movement and aggregation of labour is a factor to be considered. Much labour comes from the north-west, i.e., the neighbouring

districts of Nadia and Jessore. These labourers returning in February certainly take cholera with them.

Calcutta has had yearly and monthly a high cholera death-rate for many years. Rangoon, though outbreaks frequently occur, has not suffered to anything like the same extent. Similarly, Singapore, Bangkok and other eastern ports have never suffered such continuous endemicity, though the factors of mean winter temperature, humidity and soil moisture are every bit as suitable as in Calcutta.

Similarly, the disease, though frequently introduced into the West Indies and Central America, has never established an endemic home as it has in Eastern Bengal.

Therefore there must be some epidemiological factor peculiar to Bengal and Calcutta which fixes the disease here. Racial susceptibility, density of population, economic conditions have all been discussed above. The Indian,—from Hirsch's records,—seems to be much less susceptible than the Negro races. Jack's book shows that the economic condition is good. Density of population is undoubtedly a factor, but I believe the main one to be the habits and religious customs of the people.

In Bengal every man and woman takes a daily bath in the open,—winter and summer,—standing in the water well above the knees and at intervals completely immersing the whole body. A single cloth of some size is worn by both sexes, and it is the common practice to wash this garment at the same time in the same water. In nine cases out of ten the water for drinking and cooking is derived from the tank in which all wash. If a crowded community contains one cholera carrier, there is a daily re-infection of the water. Should a case die of the disease the body itself is in all probability prepared for funeral rites and washed on the banks of the pond or river; the clothes of the deceased person also.

In addition to the daily bath, the Hindu section of the community during their ceremonial ablutions drink of the water. In Calcutta the water of the Hooghly and Tolly's Nullah being part of the sacred Ganges is drunk by many, though there is piped water of good quality available.

That carelessness in regard to drinking water is the cause of endemic cholera is supported by the following facts:—

(1) The home of endemic cholera is in those districts where water supplies are from rivers and tanks, and where wells are not used, such as Lower Assam and South Eastern Bengal. As recorded in the *Gazetteer* of the district of Chittagong, in the two years where rivers and tanks were filled with salt water during a tornado, there immediately followed an epidemic of cholera and the cause given is the shortage of drinking water.

(2) The reports of the Health Officer of Calcutta show that those wards which border on

the River Hooghly or Tolly's Nullah have year by year the highest cholera mortality. In his annual reports the Health Officer includes a "black list" of those wards with the highest cholera mortality, and Wards V, XXV, and XXIII, which are riparian, invariably figure in this list. He says in his report for 1922 that "the heavy incidence of the disease on Hindus whose religion enjoins bathing in the river and Tolly's Nullah corroborates his view that a large proportion of the cholera of Calcutta is water-borne. Besides the tanks and river the unfiltered water-supply intended only for flushing drains is freely used by the ignorant and careless for domestic purposes."

Summary and Conclusions.

1. India may still be regarded as the home of cholera and deltaic Bengal may still be considered the endemic home where endemic cholera is just as regular and severe as ever.
2. That there is a fair body of evidence to show that cholera in the rest of India is dependent on cholera in Bengal, but owing to increased facilities for and rapidity of travel, it is not so easy to trace the spread.
3. Why deltaic Bengal is the endemic home of cholera is not proved. It is obvious that density of population, conditions of humidity of air and soil, and of winter and summer temperature are suited to the requirements of the infecting agent, and that the notorious carelessness of the people regarding their drinking water favour its spread; but we want to know to what extent the "chronic carrier" exists.
4. That the deltaic region of Bengal is the place where cholera should be attacked. Of all preventable diseases cholera is the easiest to tackle, and could we get to grips with it in this region, we might ultimately wipe it off the earth.
5. I suggest intensive vaccination in a selected district and a very rigorous propaganda campaign. If this is successful, to extend it throughout the province.
6. It is our very obvious duty to take the most stringent measures at our ports and frontiers to prevent the spread of the disease.

PRELIMINARY OBSERVATIONS ON ACQUIRED DISEASES OF THE HEART AND AORTA AS MET WITH IN BENGAL.*

By UMA PRASANNA BASU, M.B., M.R.C.P. (Ire.),
Teacher of Medicine, Calcutta Medical School.

THE observations I have recorded in this paper are based upon a series of 446 cases examined by me during the course of hospital and private practice in this city, extending over a period of ten years. From the table containing the statistics of the different varieties of cases it will be

* Being a paper read at a meeting of the Medical Section of the Asiatic Society of Bengal on the 11th of March, 1925.

TABLE.

*Disorders of the Heart seen in Bengal from July 1915 to March 1925. 446 Cases.**Different Varieties.**Numbers.*

evident that structural lesions of the heart and aorta due to acquired diseases as met with in Bengal differ as widely from those that are seen in the different clinics of Europe as the hieroglyphics of Egypt differ from the picture writings of Mexico.

Chronic endocarditis, whether in the young or in the old, which is so frequently seen in Europe is certainly less common in Bengal. Consequently the familiar red faces of mitral disease and the staring looks and pale appearance of aortic regurgitation so common in the clinics of Europe are conspicuously rare in Bengal; the former is rare because rheumatic fever which is, *par excellence*, a disease of the cold climate is a rare affection of the people of this province; the latter is less common because granular kidneys, alcoholism and athletic strain are much less

often observed here than in Europe. The degenerative type of chronic endocarditis is also seldom met with as the majority of the people of Bengal hardly attain that age in which it is commonly prevalent. In cases of rheumatic endocarditis seen in Europe the prognosis is very often grave because the infective process—like pneumococcal infections—has the morbid tendency to recur, and we are fortunate in this country in this respect as recurrences are comparatively infrequent; yet in spite of this, chronic endocarditis—whatever may be its ætiology—very often runs a rapid course and compensation soon fails, which is just the converse of what is generally seen in Europe. Another type of acquired chronic endocarditis which I observed in my series was the idiopathic variety which affected chiefly the young males and sometimes

the females, and which damaged either of the two orifices almost equally and in whom rheumatism and syphilis could be definitely excluded.

In the ætiology of acute endocarditis in Bengal in my series of cases, influenza, small-pox, measles, diphtheria, typhoid fever and sometimes streptococcal infections—specially when of puerperal origin—ranked next to rheumatic fever in their respective frequency in the order in which they have been mentioned. In the case of enteric where acute endocarditis was present it could be attributed to the secondary streptococcal invasion.

For obvious reasons rheumatic pericarditis was rare, and when present very often co-existed with myo- and endocarditis. In a few cases of nephritis it was seen as a terminal event.

In the heart-kidney complex met with in Bengal the heart is responsible for the kidney disease in many cases, which is just the opposite of what is commonly seen in Europe.

If we define angina as coronary sclerosis then, of course, such anginas are seldom met with in this soil as it very often consorts with arteriosclerosis which is comparatively rare. If on the contrary, as I pointed out a few years ago, we look upon the symptom-complex as an expression of exhaustion of the heart muscle then such anginas—for reasons given below—are by no means uncommon.

The extra-systoles observed in my series of cases were to a great extent of reflex vagal origin. The eccentric heart manifesting such arrhythmias as paroxysmal tachycardia, auricular flutter and auricular fibrillation was rare compared with those seen in Europe. A notable feature in some cases of auricular fibrillation that came under my observation was absolute regularity of the pulse in striking contrast with the occasionally irregular pulse very often seen in such arrhythmias. And from what I have seen of these irregularities I can definitely say, from the polygraphic tracings I took of some of them, that such irregularities could often be linked in one chain. The different types were but manifestations of different grades of one and the same disorder which was very often an eccentric focus of irritation within the heart muscle. When that focus was mild it produced extra-systoles; when moderate, paroxysmal tachycardia; when severe, auricular flutter; and when serious, fibrillation.

Real cases of complete heart-block and Stokes-Adams' disease were very rare, and for the former malady—when present—syphilis was mainly responsible. Partial heart-block as the result of such infections as pneumonia, typhoid fever, bacillary dysentery and very rarely malaria was certainly not uncommon. Bradycardia purely due to high arterial tension—so common a feature in the European clinics—was seldom seen.

The poisoned heart of Graves' disease was very occasional. Seeing that the principal types of diseases of the heart prevalent in Europe were uncommon in my series of cases, it might

very well be asked "Is heart disease then uncommon in Bengal?" No! The majority of the people of Bengal suffer from one of the most serious types of heart lesion, namely, myocardial disease of the heart. We all know by this time that the endocardium constitutes anatomically a very small portion of the heart, and that the prognosis of endocarditis depends largely on the condition of the myocardium. It is this vital structure that is the seat of disease in the overwhelming majority of the cases seen in Bengal. It is not, strictly speaking, a myocarditis but a degeneration of the myocardium absolutely independent of coronary sclerosis, and this degeneration is responsible for the early death of its people. It symptomatically manifests itself in the lack of physical endurance so well known amongst the Bengalis that it hardly merits a detailed description. Clinically it attracts the notice of the physician by a rapid rate of the heart, the pulse very often ranging between 80 to 90 per minute at rest. Some degree of hyperæsthesia over the precordium was present in many cases. The apex beat was very often difficult to localise, X-ray examinations seldom revealed dilatation, On auscultation the first sound was very often muffled and tonic murmurs, as was pointed out by me some time ago, indicating a toneless flabby myocardium could often be heard, as also the basal systolic murmurs. In a limited number of cases the pulmonary second sound was also accentuated. Such patients very often exhibited effort syndrome.

It is thus evident that there is a fundamental difference between the types of heart disease prevalent among the inhabitants of the countries in question. And what constitutes this difference?

The cardinal factor responsible for this difference is the climate. This was very ably pointed out as long ago as the year 1910 by Lieutenant-Colonel J. W. D. Megaw, I.M.S., in an excellent paper on this subject contributed by him to the *Indian Medical Gazette* for March. He said "debilitating climatic conditions are distinctly calculated to bring about early enfeeblement of the heart"; the reference was to Anglo-Indians and domiciled Europeans. There could be no gainsaying that high air temperatures produced vasodilatation which threw greater work upon the heart and thus drew largely upon the cardiac reserve. It made the people lazy and lethargic, the majority of whom consequently did not take proper exercise and thus rendered the ill-nourished heart—like the arm in a sling—to waste from want of proper blood supply. The factor next of importance in the production of a degenerated myocardium is the poverty of the masses from dearth of industrial developments in this country. As a matter of fact, the chief disease of Bengal is inanition. Poverty demoralises the myocardium chiefly in two ways, the first of which is the inferior quality of the food that is consumed,

While I do not concur with Lieutenant-Colonel D. McCay that the nitrogen-poor diet markedly affects the physical growth of the people of Bengal for the simple biological reason that the elephant, whose diet is certainly poorer in nitrogen than the tiger's, is unquestionably much more developed than the tiger, I fully agree with this eminent observer that large quantities of unassimilable proteid in a Bengali diet leave enormous nitrogenous residue in the intestines which furnishes a fruitful source of intestinal putrefaction and toxæmia; nor is the quantity of food which is necessarily enormous less important in this direction. Such monstrous alimentation leads to visceroptosis and intestinal stasis. The natural consequences of such a diet are intestinal catarrh and diarrhoea, dysentery, and septic ulceration of the gums—all of which are well-known common disorders of Bengal. The combined effect of climate and poverty leads ultimately to a change in the physiology of the Bengalis materially from that of the Europeans, and such changes in the blood as diminution of the percentage of hæmoglobin are well known. Since in the effective maintenance of pressure in the tubes the condition of the pump is important, we find a low blood pressure amongst the Bengalis which is the direct result of a myocardium which is ill-nourished as a result of anæmia consequent upon the gastro-intestinal infections noted above.

The climate also markedly changes the pathogenesis of diseases present in the two countries. Indeed, Bengal is the best natural incubator I have ever known for the growth and development of bacteria on account of its heat and moisture. All the four scourges of Bengal, namely, cholera, dysentery, malaria and kala-azar damage the myocardium, whose vitality—for reasons given above—has already been sapped. A vicious circle is thus established—anæmia, infection anæmia—and the heart thus becomes progressively weak. Infection damages the heart in two ways; in the first place due to temperature which quite apart from the insufficient food and imperfect metabolism it enforces upon man, directly damages the delicate parenchyma and indirectly exhausts the heart by vasodilatation. The next factor is the toxin which acts directly on the cells and indirectly by the resultant hæmolysis and anæmia. Such infections as beriberi and very often filarial fevers do not spare the myocardium, and if they are less important than those mentioned above, it is because their incidence is less. The infrequent consumption of alcohol by the Bengalis is of no advantage to the heart muscle as it is made worse by the various forms in which tobacco is used, as also opium and in some cases, at least, *bhāng*.

It thus happens that infections common to all climates, such as influenza, pneumonia, enteric and diphtheria, which are notorious in attacking the cardiac musculature—when they visit the Bengali homes find a ready soil and often create

disaster. The Bengalis thus die prematurely as the result of such infections as compared with the Europeans who, as a rule, stand infection better and attain to a much older age.

What the exact nature of changes in the myocardium is, I shall be able to say at a later date when I have concluded my observations on the pathological examination of the cardiac muscles of the Bengalis, the investigation of which I am at present engaged in.

A NOTE ON THE EFFICACY OF NEEM-BATTIS IN THE DESTRUCTION OF RATS AND RAT-FLEAS IN RAT BURROWS.

By C. D. TIWARI, M.B., B.S., D.P.H.,
and

R. B. LAL, M.B., B.S., D.P.H., D.T.M. & H.
(From the Epidemiological Bureau, Punjab, Lahore.)

WHILE conducting some experiments on disinfestation of houses by fumigation with substances like cresol it was found that the fleas in the rat-holes were not killed and the rats were not at all affected. It would, therefore, seem reasonable that the rat burrows being the most likely places to harbour fleas, would act as protected reservoirs for these insects; which would infest the room after the disinfestation was over and thus defeat the object. In order to kill the rats and fleas in the burrows, Lane (1914) devised the *neem-batti*. A standard *neem-batti* as issued from the Punjab Plague Equipment Depot, Jullundur, is prepared as follows:—

Pot. chlorat. 2 dr., Pot. nit. 1½ dr. and sulphur 2 dr. are powdered together and mixed with 5 dr. of oil (any kind *Taramira-mustard*, castor-oil, etc.), to form a paste to which 1 dr. of chilli-powder (red pepper) and a handful of crushed dried *neem* leaves (*Azadirachta indica*) are added. A wick of about 9 inches, made of thick cloth (*khaddar*) is soaked in saturated solution of Pot. chlorat. The paste as prepared above is put over

the wick leaving exposed about an inch of one end. The wick is then encased in cloth and a piece of thick paper wrapped over it. To use a *neem-batti* all openings except one opening of the burrow are closed; a *neem-batti* is then ignited and introduced into the open hole which is then similarly closed.

Under instructions from the Director of Public Health, Punjab, we conducted a series of experiments to study the efficacy of *neem-battis* in destroying rats and rat-fleas.

The experiments were carried out in natural rat-holes in the open fields which were found to be more convenient than the burrows in houses.

In order to determine the nature of the burrows thirteen rat-holes in alluvial soil were dug up and carefully examined. It was found that

VARIOUS TYPES OF RAT BURROWS.

they were variable in dimensions and designs and could be classified under the following groups:—

1. A simple oblique blind hole (Fig. 1).
2. A blind hole with a side pocket (Fig. 2).
3. A burrow with two or three openings with or without pockets (Fig. 3).
4. A complicated burrow formed by the intercommunication of two or three burrows (Fig. 4).

The diameter of the openings was between $1\frac{1}{2}$ inches to 3 inches and the maximum depth below the ground was 3 feet. The distance

between two openings varied from 2 to 8 feet.

General plan of experiments.

A rat-hole was selected in the field and all the holes near-by, except one, were closed with iron sheets and clay. Two rats with living fleas on their bodies were let in through this opening. A *neem-batti* was then lighted and introduced into the hole which was then similarly closed. The *batti* was allowed to smoulder in the closed burrow for varying periods of 5 to 10 minutes. The burrow was then dug up and search was made for the rats and the fleas and their condition was noted.

In a series of eight experiments conducted in burrows of all types, in four of which the *batti* was allowed to smoulder for 5 minutes and in one each for 6, 8 and 10 minutes, the rats and the fleas on the rats in all cases were found dead. Figs. 5, 6 and 7 show the situations in which the dead rats were found. It was also noted that every nook and corner of the burrow was blackened with smoke showing thereby that the smoke had penetrated all parts of the burrow.

Standard *neem-battis* and black rats (*Rattus rattus*) were used in all these experiments.

CONCLUSION.

Fumigation with *neem-battis* in the way described above kills the rats and the fleas on the rats in the burrows in the fields in 5 minutes.

CERTAIN ASPECTS OF LITHOLAPAXY.

By R. W. ANTHONY, M.B., C.M., F.R.C.S.E.,
LIEUTENANT-COLONEL, I.M.S.,

(Lately Civil Surgeon, Hyderabad, Sind.)

My attention was directed some months ago to the article on litholapaxy by Lieutenant-Colonel A. J. V. Betts, I.M.S., in the *Indian Medical Gazette* for April, 1924. He gives a very lucid description of the operation, and I only write in the hope that my experience may help those not very familiar with the operation in one or two directions not dealt with fully by Lieutenant-Colonel Betts.

First as to my credentials: I have done over 2,500 litholapaxies mostly at Hyderabad-Sind which has attracted patients for this operation for some decades now. It has been the custom there to treat cases of vesical calculus as out-patients. The stone is crushed and the patient allowed to go home when he has recovered from his anæsthetic. I feel sure they would resent having to stay as in-patients now in any uncomplicated case.

In Sind, as elsewhere, stone is very common in children. I think the operation is easiest in them as one practically never has to deal with a bladder which has become loculated and out of shape. Unless they are deeply anæsthetised, however, they are very apt to strain and void the water which has been put into the bladder as a preliminary to crushing the stone. For this reason I have made it a practice to tie a bit of fine rubber drainage tubing round

the base of the penis. Thicker tubing is used for adults.

The small size of the urethra is a difficulty. For some years past I have been in the habit of dilating the urethra with Liston's graduated metal bougies. In a boy of 2 years of age a 4-7 passes as a rule with ease and the urethra can nearly always be persuaded to take a 5-8. If it does one can work very comfortably with a No. 6 lithotrite. If it can only be dilated up to No. 7 one has to use a lithotrite smaller than No. 6 and even then it fits too tightly for comfortable working. Of course no force must be used in the dilatation. Personally I have never ruptured a urethra.

In catching and crushing the stone and its fragments I think it unwise and unnecessary to rotate the beak of the instrument to one or other side. If the fragment is not exactly where you expect it to be, i.e., at the most dependent spot, it must be close to it to one or other side or in front or behind, and one can easily investigate these areas by slight movements of the handle to one or other side or by elevation or depression, the female blade being kept always on the floor of the bladder. Indeed, particularly in children, I have found this the most sensitive method of dealing with the last crushworthy fragment. I sometimes find a fragment thus after I have imagined the bladder to be clear with a sound.

The first litholapaxy operation I saw done was by the late Colonel Henderson, I.M.S. I wondered why when he had obviously caught a fragment he yet withdrew the male blade a little way once or twice and brought it down sharply again on the fragment. He explained that it was to make sure that no mucous membrane had been caught. When there is nothing but a fragment of hard stone in the jaws of the instrument there is, of course, no sensation as of a piece of interposed soft tissue. Doubts on this point are settled by the manœuvre I have mentioned. Especially in a fasciculated or pouched bladder the danger of catching mucous membrane is by no means negligible. I have not seen this point touched on in any of the literature on the subject which I have read.

In children I have derived no advantage from the use of an evacuator. I can clear the bladder quicker by repeated filling and pressure over the bladder with the hand, the largest cannula passable being used. In bigger children, and if I have several stones to crush, I press out the fluid from the bladder with my left elbow applied over the pubis. It is a great saving in muscular effort. In adolescents and adults if I can pass a No. 12 or larger cannula I find the evacuator saves time and effort. As one acquires experience the scope of litholapaxy widens. I do suprapubic litholapaxy in about 1 per cent. and perineal litholapaxy in about

2 per cent. of cases now. Large size and hardness can nearly always be overcome. If the lithotrite will not lock I use a hammer. A few sharp taps will tell you if you are making any impressions on the stone. If you are using the largest lithotrite that will pass and the hammer does not help you, you must, of course, do the perineal or suprapubic operation. Phosphatic stones are easily dealt with by hammering. Uric ones often disintegrate and become less in diameter with patience and perseverance, but the expedient is of little use in the case of a large mulberry calculus. Such may be dealt with a No. 18 lithotrite and a hammer by the perineal route.

In hammering one keeps the caught stone pulled well forward, of course, and gives sharp taps on the top of the handle with the hammer. A heavy blow would drive the instrument and stone so far back as to injure the back of the bladder. In hammering with the ordinary lithotrite the difficulty is to keep the stone in the jaws of the instrument. One does it rather ineffectually by means of the thumb and index finger of the left hand on the screw thread. Also one is apt to injure the turning wheel with the hammer. I interviewed Weiss & Sons last year, and they are making me a No. 16 lithotrite in which the stone is kept gripped by means of a spring and which has a suitable anvil head for the hammer.

If the size of the stone necessitates it I use the hammer with even so small a lithotrite as No. 6. In this case, of course, the taps with the hammer have to be light. One soon sees if the stone is disintegrating and so making it likely that further cautious hammering will enable one to lock the lithotrite and crush the stone in the ordinary way.

CELLULITIS OF THE ORBIT.

By R. E. WRIGHT,

MAJOR, I.M.S.,

Superintendent, Government Ophthalmic Hospital
and

Mr. C. G. TAYLOR, I.M.D.,

Assistant Superintendent, Government Ophthalmic Hospital, Madras.

CELLULITIS of the orbit is a condition of great practical importance not only to the eye specialist, but also to the general practitioner. In a large number of cases if the condition is not diagnosed correctly and treated promptly, the vision, if not the eye itself, is lost. This is a serious matter although insignificant as compared with the loss of a life which must also be kept in mind as a possibility not too remote. It does not require very extensive surgical preparation to explore an acute orbit and there is no reason why it should not be undertaken successfully by the practitioner with the apparatus ordinarily at his disposal provided he knows how to go about

it. We have seen both eyes and lives lost through ignorance of how to deal with such cases and, as the condition is not rare, it may prove helpful to consider (even in a superficial way) some of the features which appear to us of practical value.

In speaking of orbital cellulitis we include not only diffuse and localised inflammation of the cellular tissues of the orbit, with pus formation, but also inflammations of the periorbita, subperiosteal abscess, and thrombophlebitis.

First it is essential to know something of the anatomy of the parts concerned. Surrounding the orbit on three sides, we have the accessory sinuses of the nose. The intervening bony wall is covered on the one side by the periorbita and on the other by mucous membrane. The inner bony wall presents many sutures where the periorbita is bound down and cannot be as readily elevated as on the roof or floor. This wall is very thin and may show dehiscences. In relation to it from before backwards, we have the frontonasal duct, the anterior, middle, and posterior ethmoidal cells. The frontal sinus is related to the roof, the maxillary antrum to the floor. Between the orbital rim and the globe in the superior temporal quadrant lies the lachrymal gland. In the superior nasal quadrant we have the superior orbital vessels and nerves, the trochlea, the tendon of the superior oblique, and the venous connections between the ophthalmic and angular veins. In the inferior nasal quadrant is the lachrymal sac, but it is sunk in its groove and covered with a fascia level with the bone. Here also is the inferior oblique stretching between the wall and the globe. The globe and its four recti form a cone which lies separated from the walls by a considerable interval, bridged across by the superior oblique tendon and the inferior oblique. The levator palpebrae superioris lies closely associated with the superior rectus posteriorly, forming part of the cone, but its tendon runs forward anteriorly in front of the conjunctival fornix into the lid. An incision deep into the superior fornix towards the orbital rim would cut it. It forms a plane between the muscle cone proper and the roof. The belly of the superior oblique stretches close to the bone along the angle between roof and inner wall from the trochlea to the apex of the orbit. It may be seen, therefore, that a free incision through the conjunctiva, except in the inferior temporal quadrant, would be liable to injure the structures referred to. Hence deep exploration through the conjunctiva is better attempted with a needle, or through an incision extended by a sinus forceps. Another interesting anatomical consideration is the connections of the orbital veins. Without going into details which may be culled from text books of anatomy, these may

be considered in several groups. The veins which connect up the orbit with the nasal sinuses; those which form anastomoses with the pterygoid venous plexus, and hence with the drainage areas of the tonsils, alveolar regions, and teeth; and those which link up with the superficial veins of the orbital region, notably the connections of the angular vein. One outstanding feature in considering the veins is the fact that the superior and inferior ophthalmic veins drain directly into the cavernous sinus, and that the former arises from two branches which enter the orbit above the internal tarsal ligament from the superior orbital and angular veins respectively. Hence blood from the lids and the orbicularis area as well as the superficial tissues of the nose, brow and cheek, may find a way through the orbit to the cavernous sinus.

Of the common causes of cellulitis met with here, infective processes originating in the nasal sinuses form a very important group. Our experience goes to show that infection of the ethmoidal cells is most liable to lead to invasion of the orbit; next in order come the frontal and sphenoidal cells, and lastly the maxillary antrum. For the most part then in orbital cellulitis due to nasal sinusitis, we are concerned with the superior and mesial walls and the apex of the orbit. A direct extension from the frontal sinus through the bone frequently results in a subperiosteal abscess which strips the periorbita from the roof and tends to point forwards beneath the brow above the plane of the levator. Such a condition is comparatively easy to deal with if seen before it bursts through the base of the lid. If it has opened thus spontaneously it may be difficult to prevent ectropion. When the ethmoidal cells are involved, however, it is frequently more difficult to form a diagnosis. For anatomical reasons given above, namely, the way in which the periorbita is adherent at the sutures of the inner wall, there is more commonly an invasion of the orbit rather than a formation of subperiosteal abscess. Apart from direct extensions via bone and periorbita, nasal sinusitis may lead to infection of the orbit through the venous channels which have been considered above. An infective process having penetrated the wall direct or by the vessels, may either form a definite abscess or a more diffuse cellulitis, largely dependent on the nature of the infecting organism. The veins may become extensively involved in which case one speaks of a thrombophlebitis. In either case there is the possibility of the channels leading to the cavernous sinus carrying the process to that important structure. Infections of the skin over the orbicularis region and the nose such as boils, styes or diffuse erysipelatous conditions may give rise to thrombophlebitis and cavernous sinus-thrombosis. A thrombophlebitis may, of

course, take place in the opposite direction (from the cavernous sinus to the orbit) as for instance in cases of middle ear infections. Other sources of local pyogenic infection are dental (maxillary) and tonsillar sepsis, and perforating injuries. Occasionally metastatic pyogenic infection occurs from a distant focus, and both syphilis and tuberculosis may attack the bony wall and its periorbita and extend to the orbit itself. Of the frontal sinus conditions associated with orbital abscess, syphilitic osteitis and periostitis with empyema is perhaps the commonest, but this is not of bad prognosis in so far as the eye is concerned. The abscess may point under the skin of the forehead or into the orbit and come forward along the levator just below the orbital rim. One must bear in mind that there are many cases of proptosis with chemosis, redness, and pain, which are not due to an infection of the cellular tissues of the orbit in its true sense. A slightly proptosed, highly inflamed eye may be due to tenonitis. Here the peculiar yellow colouration, boggy swelling of the conjunctiva, and the intense pain on moving the globe are suggestive. We have seen such conditions result from the careless use of subconjunctival injections, and in hospital practice one must be alive to this sequence as patients seeking advice at the hospital conceal the fact of previous injections. Acute lachrymal retention (dacryops), rapidly growing malignant tumours pushing forward under an inflamed conjunctiva, inflamed hydatid cysts, or *Cysticercus cellulosa*, and panophthalmitis with a marked circumbulbar reaction, may all prove puzzling at times. Possibly the greatest practical difficulty in differential diagnosis is to distinguish between syphilitic osteoperiostitis and a subperiosteal abscess or cellulitis. It is of great importance to be able to do so, because syphilitic osteoperiostitis will quickly respond to suitable medication provided it has not already established a purulent sinusitis requiring nasal draining. Syphilitic inflammation of the periorbita and bone is of slow development; proptosis is less and there is marked localised tenderness of the bone, but of course this may not be detectable if there is a small posterior area of deep inflammation. In case of doubt it should not be forgotten that it is an easy matter to explore the orbit with a needle. The superior and inferior temporal quadrants may be searched freely through the conjunctiva right back towards the apex. It is a more difficult matter to explore the inner wall satisfactorily, but it can be done by passing the needle back parallel to the wall of the orbit above or below the caruncle. When pus is located then it will become necessary to expose freely the infected area. If pus is not located, it is for the most part better to open up the suspected region in a further endeavour to trace the focus

of inflammation and relieve tension. In either event the route to be followed is the same. If assured therefore that there is a septic process taking place in the orbit or if in doubt the safest procedure is to open it up freely and examine right back towards the apex. This leads us to the methods of opening the orbit which constitute the most important line of treatment of orbital cellulitis. To explore or drain the outer aspect of the orbit one may make a curved incision through the outer third of the brow parallel with the orbital rim and a short distance outside it, carrying the incision just below the canthal line over the malar bone, cutting through the skin and subcutaneous tissues right down to the periosteum. The latter can be carefully elevated as far forward as the orbital rim, and thence the periorbita separated both from the outer part of the roof—the outer wall—and the floor. In this way access may be obtained to a considerable portion of the orbit and it is a perfectly safe procedure. If nothing is found no harm is done and no deformity is caused in so far as the lids are concerned. If it is wished to extend the investigation, the outer bony wall may be removed to a greater or lesser extent. It is, on the other hand, a very undesirable procedure to make an incision through the skin parallel to the lower rim of the orbit because one is very liable to get lower lid adhesions and late ectropion. The floor can quite readily be explored and drained through the external incision. A pointing abscess may, of course, be evacuated through an incision in the conjunctival fornix and further extended with a sinus forceps, but such an opening tends to become valvular and the lid may hinder the escape of pus. In such cases it may be necessary to do an external canthotomy to relieve the tension of the lids and prevent the retention of pus. Exploration of the roof of the orbit may readily be made by incising the brow to the outer side of the supra-orbital notch, elevating the periosteum round the rim, and following it backwards along the roof. A most useful route of exploration and drainage is by the superior nasal quadrant which may be reached through a curved incision parallel to the orbital rim, starting just below the inner end of the brow mesial to the supra-orbital notch and continuing down the side of the nose half way between the attachment of the internal tarsal ligament and the middle line. The periosteum may then be separated back over the area between the supra-orbital vessels and the tarsal ligament. This must be carefully done, the trochlea being elevated with the periosteum and access thus obtained to the inner wall of the orbit. After the trochlea has been elevated care must be exercised in proceeding backwards. In the angle between the roof and the inner wall it is easy to progress towards the apex, but lower

down it is difficult to strip the periosteum without doing considerable damage. This method of approach to the inner wall of the orbit, the inner half of the roof and the orbital apex does not lead to subsequent deformity, it has the advantage of enabling the operator to deal with the frontal sinus and also the ethmoidal cells should they be involved. Such measures are infinitely preferable to making tentative explorations with a narrow knife through the conjunctival sac, and unless pus is definitely pointing in the conjunctival fornix such a procedure does not give sufficient drainage and relief from tension. A frontal sinus abscess which bursts through the roof of the upper lid may come to a natural cure without producing any very great deformity, because adhesions between the orbital rim and the tissues of the upper lid do not tend to cause such serious ectropion and exposure as scar tissue formation in the lower lid: still incisions through either lid should be avoided. Having made arrangements to drain the orbit it is of course necessary to deal with the source of the infection. Should this be of sinus origin, suitable drainage into the nose must be arranged for. If cavernous sinus-thrombosis sets in one is not left long in doubt and treatment is of no avail. The other eye becomes proptosed and cedematous and the patient dies. In cases of syphilitic osteoperiostitis and diffuse gummatous infiltration of the orbit, the free exhibition of antisyphilitic remedies quickly improves the condition.

The following cases illustrate some of the points mentioned above:—

LOCALISED CELLULITIS OF THE ORBIT WITH ABSCESS.

Case 1.—R., Hindu male, age 20, admitted on 25th May, 1924, with cellulitis of the orbit. History:—On the 12th March, 1924, a white spot appeared on the right cornea for which he was treated by subconjunctival injections. On 17th May, 1924, a few hours after the 12th injection the eye became swollen, protruded and very painful. For several days the eye was treated, and on the sixth day the doctor performed an exploratory operation, but no pus was found. On the eighth day the patient was admitted to this hospital and the orbit explored with a needle, with negative result. Pressure on the cornea was considerable and a transverse corneal erosion had formed just below the margin of the upper lid, so the patient was given an anæsthetic, an external canthotomy was performed and further exploration in the superior nasal quadrant revealed pus in the inner side far back. Exposed bone was felt near the apex of the orbit. Free drainage was effected; but eventually the eye was lost and had to be removed. The chief point of interest about this case is that the cellulitis supervened on subconjunctival

medication. If the condition resulted from subconjunctival injection introduced by a needle, it is hard to say why the main focus of suppuration should be so far back in the posterior ethmoidal region; possibly it was only a coincidence, or the infection may have travelled backwards by the venous channels. Had the abscess been evacuated in time, the eye might have been saved.

DIFFUSE CELLULITIS OF THE ORBIT.

Case 2.—T., Hindu female, age 16, O.P. No. 8875, was admitted on 6th June, 1924, with marked swelling, proptosis and chemosis of the right eye, and a history of having scratched a pimple on the tip of the nose on 1st June, 1924. By 4th June, 1924, there was marked swelling and pain with a bulging forward of the eye and an inability to close the lids. On 5th June, 1924, the conjunctiva was incised by a practitioner. On 6th June, 1924, the patient was brought to hospital and under chloroform the orbit was carefully explored with a needle. There was exposed bone in the superior nasal quadrant, but no pus. A free incision was made in the superior nasal quadrant, and external canthotomy was performed. The temperature at this time was very high and the patient had great pain and was inclined to be delirious. The temperature was controlled by ice packs. On 8th June, 1924, the temperature was still keeping up to 104°, and she complained of great pain on the right side of the head. There was marked swelling at the right side of the neck and parotid region. It was decided to explore the outer aspect of the orbit and a curved incision parallel to the orbital rim was made down to the periosteum which was then elevated from the outer wall. The outer wall was removed to the spheno-maxillary fissure and the pterygoid region exposed. No pus was found, but there was considerable reduction in tension and on 10th June, 1924, the patient's condition was slightly better. At this time the patient experienced great difficulty in swallowing, and it was found that there was marked swelling of the right tonsil, soft palate and the pillars of the fauces. The upper part of the tonsillar region was incised, and the enormously-swollen uvula removed. No pus was encountered. On 13th June, 1924, the patient received antistreptococcus serum and she showed distinct improvement on 14th June, 1924 and 15th June, 1924. On 16th June, 1924, the temperature rose again to 105°. Antistreptococcus serum was exhibited on the following day, and the patient treated by ice packs and cold sponging. There was marked abdominal tenderness and meteorism which was relieved by turpentine enemata. On 18th June, 1924, the temperature fell and continued to drop steadily until it came to normal about the 28th of the month. Meantime the globe itself had become infected through the

corneal ulcer, and the eye was eviscerated when the patient's temperature had come to normal. Early free incisions might possibly have saved the eye in this case. Fortunately streptococcal infections of this serious type are uncommon.

CAVERNOUS SINUS-THROMBOSIS.

Case 3.—A., Hindu male, age 22, O. P. No. 17594, admitted on 21st October, 1924, with high temperature and slight delirium, and marked swelling of the subcutaneous tissues about the right orbit, more particularly over the glabella where the skin was raised and fluctuating. Two or three small openings exuded pus near the tip of the nose and pus came from the right nostril. There was slight proptosis. The veins of the sclera and conjunctiva were engorged and the supra-orbital vein was full. An incision was made along the middle line of the nose down to the bone which was rough, the periosteum having raised by pus. The incision was carried round the orbital rim in the brow. Two other incisions were made on lateral aspects of the nose, the inner wall of the orbit was explored and pus found. Ophthalmoscopic examination of the right eye was impossible owing to the exposure ulcer. Examination of the left showed slight redness of the disc, no œdema. The pupils were active to light and inclined to be contracted; temperature 104° , pulse very rapid. The following morning there was a definite fullness of the subcutaneous tissues of the left eye, but no proptosis of the globe. The mental condition was much worse. The patient continued to sink and died at 5-40 P.M. on 23rd October, 1924.

Post-mortem Appearances.—There was suppurative ethmoidal sinusitis, purulent infiltration of the orbit with phlebitis and clots in the vessels. The cerebral veins were markedly congested and the brain was œdematous. There was a large area of purulent exudate beneath the membranes over the temporosphenoidal lobe. A considerable quantity of green pus lay round the infundibulum. The cavernous sinuses were filled with pus and clots. The infective process had extended into the rolandic area and also back beneath the tentorium and up towards the posterior region of the cerebrum on the right side. The left was not so extensively involved. The organisms found in the smear from the meningcal exudate were staphylococci and pneumococci.

THE ART OF THE INDIAN CHIROPODIST.

By R. L. SPITTEL, F.R.C.S. (Eng.),
Surgeon, General Hospital, Colombo.

IN Ceylon the itinerant Indian chiropodist enjoys a reputation for the removal of corns that surgeons might well envy.

The public, having come to consider corns as being more within the sphere of the chiropodist than the surgeon, seldom consult the latter for the ailment; and even when they do, the surgeon, more often than not, contents himself with prescribing salicylic collodions, corn-shields, or plaster-mulls—palliative measures at best—instead of performing a simple and radical operation.

Chiropody in the West stands on some foundation of pathology and asepsis. In the East it lies in the hands of ignorant individuals who, apart from any pretensions to asepsis, ignore even the rules of ordinary cleanliness, both in their person and procedure. It is all the more remarkable, therefore, that these quacks enjoy the vogue they do even among Europeans who do not grudge to pay them as much as five rupees for the removal of a single corn.

The chiropodist comes to your door carrying a little handbag—the only respectable thing about him. He submits for your inspection a number of letters of recommendation from his various patrons, telling, in more or less enthusiastic terms, of corns that have both been extracted and exhibited.

1.—A sharp oblique-edged chisel.
2.—A probe.
3.—A horn cup tipped with wax.

His *armamentarium* consists essentially of three implements:—(1) A sharp oblique-edged chisel, fashioned from the back of an old Kropp razor; (2) a probe; and (3) an assortment of conical horn cups, made from the hollowed ends of the antlers of some species of deer: these have a minute hole at the apex, and are capped with wax.

His method of *diagnosis* is simple. Running his hands over your feet, he pinches up

between thumb and forefinger any suspicious spot; should you wince when he does this, it is a corn he holds; if not, a mere callosity. He thus quickly demonstrates to you some four or five corns, where you thought you had only one. (Incidentally, payment depends on the number of corns removed.)

The operation. Seating himself on the floor, he asks for a cup of water. He scorns preparation of any sort. Grasping the toe in his left hand, he takes the chisel in his right, and, holding it pen-holder-wise, deftly thins down the corn with a series of light oblique strokes and thrusts, gradually working towards the centre. He fingers the whittled surface from time to time, testing its pliancy. When satisfied of this, using the acute-angled point at one end of the chisel's edge, he lightly incises the centre of the shaved area, just sufficiently to draw a little blood. Then, choosing a cup of suitable size, he makes patent the hole at its apex by passing a probe through it and the overlying wax cap. He next moistens the surface of the corn with a dab of water, and placing the cup on it, applies his lips to the apical hole and makes strong suction; then, quickly desisting, he pinches up the wax, obliterating the opening and creating a vacuum. The cup sticks and is left on for about five minutes while the other corns are being attended to. Towards the end of the operation three or four such cups adorn the feet. For bunions, bigger cups are requisitioned. The cups are finally removed and placed in a bowl of water. After a while they are taken up one by one and, with the point of the probe, a long adherent blood clot is dug out of each and proudly displayed as the extracted corns which, he now assures you, will never recur. He certainly has this to his credit, that, unlike more sophisticated chiropodists, he attempts to make a complete job of it at a single sitting.

He gives no instructions as to future shoes, etc. The operation over, he wipes his chisel and cups with a dirty rag and puts them away for use on his next patient. The wonder is that infection does not invariably follow. For this the patient has his own cleanliness more to thank than any precaution taken by the operator.

Nevertheless, there can, I think, be little doubt that this little operation, crudely done though it be, almost always confers immediate relief and often permanent cure. The little incision made at the root of the corn relieving tension there and allowing for the replacement of the epidermal core by fibrous tissue is, perhaps, mainly responsible for the good result. Certain it is, that the chiropodist is not so confident in his powers that he attempts complete removal of the epidermal plug,—a procedure that would involve more bleeding and pain than his reputation would warrant.

CANINE LEISHMANIASIS IN BOMBAY.

By Lt.-Col. R. ROW, M.D. (Lond.), D.Sc. (Lond.), O.N.E.
(From the F. D. Petit Laboratory, Byculla, Bombay.)

IN an interesting communication on this subject by Khan Bahadur C. R. Avari and Lieutenant-Colonel F. P. Mackie, I.M.S., published in the *Indian Medical Gazette* for December 1924, the authors do the writer of this memoir the honour of generously referring to his films which they had seen a short time previously from the lesions of a dog under his observation. Although it is rather late in recording the notes of these observations owing to his absence from Bombay, he takes this opportunity to do so.

The animal in question is a quasi-bulldog coming from Landikotal (N.-W. Frontier, India). On arriving here early in April 1924, she was found to have extensive ulcers on the lips, ears, nose and inner canthus of the left eye (Fig. 1).

Further there were a number of non-ulcerated lesions on the inner side of the ears looking like shining buttons of the size of large peas, very similar to the non-ulcerative forms of cutaneous leishmaniasis which the present writer showed to the War Hospital Medical Society, Bombay, some years ago in an Indian soldier returning from Palestine (Fig. 2).

The character of the ulcers and the nodules suggested cutaneous leishmaniasis at a glance, although the ulcers had greatly altered in appearance by septic infection set up by constant scratching by the animal. The preliminary

diagnosis was confirmed by the microscope. The accompanying microphotographs speak for themselves (Figs. 3, 4 and 5).

The ulcers healed up by September 1924, under treatment at Bai Sakerbai Veterinary Hospital, Parel, Bombay, leaving not a single scar.

Fig. 3.

Fig. 4.

Fig. 5.

Fig. 6. (Human.)

The parasites show the morphological characters of *Leishmania tropica*. They are slightly larger in size than those found in man (Fig. 6), from

films fixed, stained and photographed under identical conditions of magnification and illumination. The cytoplasm appears not to be so dense and the micronucleus rod-like and seen always placed at an angle to the diameter of the nucleus. The parasites did not flagellate in NNN medium or Row's hæmoglobin saline prepared with rabbit's blood; perhaps media prepared with dog's blood might have given different results.

Animal experiments. Mice infected intraperitoneally did not take the infection (2 to 6 months after infection). Two pariah dogs infected cutaneously in the ear showed the following results:—

<i>Dog (1).</i>	
Infected intracutaneously.	30-4-24.
Lesion first seen as slight redness.	19-6-24.
Definite well-defined patch, size of two-anna piece raised above surface.	16-6-24. (O-bodies found).
Ulceration of the patch.	18-6-24.
Spontaneous healing of the ulcer without a scar.	5-9-24.
<i>Dog (2).</i>	
Infected intracutaneously as in dog (1).	30-4-24.
A very small flat nodule, size of split pea.	19-6-24. (O-bodies found).
Ulcerated.	5-8-24. (Very few O-bodies found).
Ulcer healed spontaneously without scar.	15-9-24.

As Avari and Mackie state in their note, canine leishmaniasis is rare in Bombay, and the nature of the lesions induced by the author and their spontaneous recovery in a short time leads one to the belief that the resistance to leishmaniasis in the pariah dog is strong. However, it is interesting to note that their dog came under observation about the same time and was found in the immediate neighbourhood of the veterinary hospital where the author's dog was kept as an in-patient. Is it possible that their dog got the infection from the patient through some unrecognised natural vector?

The morphological, cultural and infective characters of the dog's parasite seem to make it a distinct species from *L. tropica* of man.

SOME POINTS IN THE TREATMENT OF TYPHUS FEVER.

By G. R. McROBERT, M.D. (Aberd.),

M.R.C.P. (Lond.), D.T.M. & H. (Eng.),
CAPTAIN, I.M.S.,

Medical Branch, Headquarters Waziristan District,
Dera Ismail Khan.

DURING the past few years considerable interest has been aroused in the occurrence

of typhus and typhus-like fevers in India by the publication of observations by Megaw and other workers.

As a result it is now more generally realised that typhus fever is endemic in various parts of India.

In the hope that they may prove of some value to practitioners who may meet with occasional cases of typhus fever, the following notes have been extracted from my doctorate thesis written some five years ago.

Most textbooks render singularly little help with regard to the treatment of typhus fever, Osler for example merely stating that the general management of the disease is on the same lines as that of enteric fever, following up with a few remarks on the advisability of hydrotherapy and of supporting treatment.

As a result of an experience of some three hundred cases of typhus fever mainly amongst European and Indian soldiers in Mesopotamia and treated chiefly under good hospital conditions, one came to the conclusion that, although really good nursing plays a very important part in the recovery of patients from this disease, a great deal can be done to lower the case mortality by active therapeutic measures.

It is essential to realise that in typhus fever one is dealing with a disease which will last for a clear-cut definite period unlike enteric fever, in which one cannot, with any degree of certainty, predict the duration of the illness.

One can, therefore, afford to stimulate freely from a very early period in the illness, and at the Military Isolation Hospital, Baghdad, on the staff of which I worked for two years, we were in the habit of commencing the administration of digitalis derivatives and strychnine from the date of admission to hospital.

Brandy or champagne were also administered, provided that cerebral excitement was in no way increased by their use, and pituitrin came in useful to tide over emergencies.

The chief measures on which reliance was placed, however, were rigorous attention to the amount of sleep obtained by the patient during the earlier stages of his illness, the combating of the profound toxæmia by the use of normal saline solution,—often administered intravenously,—the treatment of severe headache with accompanying restlessness by lumbar puncture, and the cutting short of threatened attacks of venous thrombosis by the intravenous infusion of sodium citrate solution.

It is an unfortunate fact that it is still not generally realised that the advantages obtained by the administration of opium derivatives in the earlier stages of such acute illnesses as lobar pneumonia and typhus fever far outweigh the disadvantages.

A patient who has to face a week or two of acute illness as in typhus fever is in a much better position to stand the strain of the later stages of the disease if he has had several consecutive nights of sound sleep at the beginning of his illness.

Cold sponging, and, if the weather be not too warm, nursing in the open air or on a freely ventilated verandah are valuable aids to sleep, but experience has led one to place a good deal of reliance on morphine and atropine administered hypodermically, and to reject such drugs as paraldehyde and the bromides.

I can well remember the case of a middle-aged European physician admitted to hospital one evening suffering from typhus fever. The rash had just appeared, the patient was in a state of wild delirium and seemed very ill indeed. Enquiries made of the patient's medical attendant elicited the fact that the patient had had no sleep for over forty-eight hours. The effect of the administration of morphine sulphate gr. $\frac{1}{4}$ and atropine sulphate gr. 1-100 hypodermically and of cold sponging was most gratifying as the patient had an excellent night and was in a much better condition in the morning although still gravely ill. Later on in his illness this patient became profoundly collapsed and completely incontinent of urine and fæces, and I was quite convinced that it was only the fact that sleep was promptly induced on his admission to hospital that enabled him—with the aid of intravenous saline infusions later on in his illness—to turn the corner and slowly regain his health.

As a result of a few similar experiences I came to make an absolute rule that every typhus fever patient must have sleep every night during the first six or seven days of his illness at least, even though opium derivatives had to be employed to attain that end.

For the relief of the very severe headache of typhus fever and of great cerebral excitement lumbar puncture was employed, and the results obtained in the majority of cases were satisfactory. The marked benefit obtained from lumbar puncture as an auxiliary measure in the treatment of typhus fever cases was noted by me more or less accidentally.

During the Spring of 1918 when typhus fever was prevalent, there was also a mild epidemic of cerebrospinal fever amongst Indian troops in and around Baghdad. Several cases which turned out to be typhus fever were sent to hospital with a diagnosis of cerebrospinal fever and vice versa.

One of these was Sepoy K.C., aged 27 years. He was sent to hospital with a diagnosis of cerebrospinal fever. Duration of illness—four days. On admission—semi-conscious and very restless; kept shouting about severe pain in the head; no rash; no squint; no herpes labialis; knee jerks absent; neck very rigid;

Kernig's sign markedly positive; and plantar reflex flexor.

Blood film report—no parasites seen, apparent leucocytosis.

Lumbar puncture performed—25 c.c. clear fluid under abnormally high tension removed. Cells scanty and mainly lymphocytes. No diplococci found (culture sterile). The clear fluid after an illness of four days' duration practically ruled out cerebrospinal meningitis. Typhus fever was diagnosed, and on the evening of the following day a typical typhus rash appeared.

The remarkable feature was, however, the immediate benefit derived from the withdrawal of the cerebrospinal fluid, as the patient ceased to shout and moan about his headache and became quiet and more sensible.

As a result of this experience I successfully employed this minor operation in a number of cases and found in it a most valuable means of alleviating the distressing headache.

The needle used should be very sharp and of a much smaller calibre than those usually offered for sale,—the majority of which are more suited to veterinary than to human medical practice. The utmost care should be taken not to allow the cerebrospinal fluid to escape rapidly after the stilette has been removed from the needle.

The most valuable therapeutic measure in typhus fever appears to be the administration of normal saline solution rectally, subcutaneously and intravenously.

As our experience increased saline therapy was employed more and more often. In mild cases rectal salines were alone employed, but in severe toxic cases we resorted to other methods.

The use of intravenous saline solution in typhus fever cases occurred to Captains Nicholson and Wiseman of our unit early in 1918.

The first occasion in which intravenous saline solution was administered to a typhus fever case in our unit was in the case of a European private soldier, aged 20. Delirium occurred very early in this case; the fifth day rash was very profuse, and despite the usual stimulating treatment and administration of rectal salines four-hourly, the patient's condition steadily deteriorated and he became completely incontinent of urine and faeces. On the ninth day of the disease the patient seemed to be hopelessly moribund. Two pints of normal saline solution were introduced intravenously and the patient rallied in an astonishing manner. Improvement was maintained throughout the tenth day; there was marked weakening on the eleventh day, but the patient rallied again after another intravenous saline infusion. In all, six intravenous infusions were given, and despite the apparently hopeless prognosis the patient recovered.

The recovery of this patient induced all the members of the hospital staff who had then, and subsequently, charge of typhus fever patients to employ this method of treatment, and the results in many cases were as striking as they were gratifying. Immediate marked improvement in the patient's condition was the rule. This improvement was frequently maintained after the first infusion in case of moderate severity, but in a number of very severe cases the operation was repeated several times.

In all cases normal saline solution was administered per rectum from the second or third day onwards so long as they were retained, and in a few cases subcutaneous salines were used after the first intravenous injection.

We did not introduce more than one pint at a time into the vein if there were more basal crepitations in the lungs than usual, and in certain patients of the more plethoric type it seemed to be good practice to remove a pint of venous blood before inserting the canula for the administration of the saline solution.

In the hot weather great care had to be taken to avoid the onset of hyperpyrexia by administering the saline solution at a temperature somewhat below normal blood heat.

These methods were warmly approved of by the senior consulting physician Colonel (now Sir) William Willcox, whose daily visits and repeated clinical demonstrations and instructions laid the whole hospital staff under a deep obligation, and as a result of his advocacy of it saline therapy was introduced into other units.

In a number of cases of typhus fever the patients complained of severe pains in the calves of the legs, and one or both of the lower limbs swelled considerably and became painful to the touch. This was specially apt to occur soon after the defervescence of the fever and was due to venous thrombosis.

All typhus fever patients were given Imperial drink in as large quantities as possible during the whole course of the disease with a view to lessening the tendency to thrombosis.

When venous thrombosis threatened I administered sodium citrate solution intravenously, as recommended by Marris (1917). Its action in all cases seemed to be beneficial, and no rigors or other ill effects were noted after the use of intravenous citrate.

The tendency to the occurrence of local thrombosis and sloughing is very marked in typhus fever, and the problem of the prevention of bed-sores is a very difficult one.

With the utmost care and with the use of air pillows and water beds for specially severe cases, it was found quite impossible to prevent

the occasional occurrence of bed-sores. When such sores do occur, every precaution must be taken to guard against septic infection with spreading cellulitis and gangrene.

No mention need be made of the nursing details usual in all fever cases—attention to the regularity of the bowels, careful watch for the occurrence of bladder distention, etc., but special attention should be paid to the toilet of the mouth, as sloughing parotitis is a common complication of badly-nursed typhus fever cases.

Specific serum therapy may be of value, but in isolated cases met with in India one is unlikely to be able readily to obtain serum from a convalescent patient, and Nicolle's serum for intrathecal and subcutaneous administration is as a rule unobtainable. My own experience of Nicolle's serum has not been encouraging, but it is probable that the serum at my disposal had lost a considerable part of its potency, and it would certainly seem to be worth while to try this serum if available.

In most textbooks no mention is made of the profound mental after-effects which, in my experience, are of not infrequent occurrence. Loss of memory, nerve deafness and deficient emotional control are quite commonly found after typhus fever.

In several European cases which I followed up for two years after their original attacks of typhus fever, defective memory and slight deafness were complained of; one medical man, writing twenty months after his original attack, said: "Distinction of sounds is not so good as before my illness, and I find it harder than formerly to catch the conversation of people. I find my memory gradually coming back, but I cannot continue at serious reading for such long periods as before."

Another medical officer wrote two and a half years after his original attack: "My memory is now quite reliable, but at first I suffered from lack of recognition of time and place. Later I used to forget dinner invitations and commit social *bêtises* of that sort. I am still rather deaf."

In a number of the more severe cases which recovered, control of the emotions was markedly deficient up to the time of leaving hospital for evacuation to England or India, and a number of patients convalescent from typhus fever were in the habit of expressing like or dislike of their attendants and fellow convalescents in no uncertain terms.

One unfortunate European patient remained practically imbecile for three months, and when he left Baghdad after six months in hospital his mental powers were still very deficient.

It would appear, therefore, that "brain workers" convalescent from typhus fever should be urged to take a very long vacation and so far as Europeans are concerned, those

convalescent from typhus fever should be invalidated to Europe for a period covering at least two hot weathers.

CELLULAR ELEMENTS IN CHOLERA STOOLS AND THEIR RELATIVE IMPORTANCE IN DIAGNOSIS OF THE DISEASE.

By G. C. MAITRA,

CAPT., I.M.S.,

Research Worker, School of Tropical Medicine and Hygiene, Calcutta;

Rai LAL BEHARI GANGULI, Bahadur, M.B.,

Physician, Infectious Section, Campbell Medical School, Calcutta;

and

J. B. BASU, M.B.,

Assistant Research Worker, School of Tropical Medicine and Hygiene, Calcutta.

CHOLERA has been described as an acute infectious disease caused by Koch's *Vibrio cholerae* and characterised by a definite clinical syndrome. In the vast majority of cases as they appear to an ordinary observer it is not very difficult to recognise the cardinal symptoms of the disease, but to associate them with the presence of Koch's comma-vibrio is by no means an easy task. It requires a good deal of technical skill and previous experience to cultivate and isolate cholera vibrio successfully from the majority of cases. Nevertheless, in spite of all the experience and skill that is brought to bear on the investigation a comparatively large number of cases remain culturally "negative."

Is one justified in declaring that such cases are not suffering from cholera?

With a view to elucidating this point we have systematically studied for the last eight months 550 cholera cases, of all degrees of severity, admitted into the Campbell Hospital, Calcutta, and have analysed the different clinical, microscopical and cultural findings in order to determine a common and constant factor which would successfully lead to an early and easy diagnosis of practically all cholera cases—both mild and severe.

In our endeavour to find out this common factor we first established all our cases in the present series on undisputed bacteriological evidence; we then worked out the percentage of cases which showed each of the following three features:—

1. Presence of comma-vibrio in the film preparation of the stool.
2. Presence of concentration of blood as shown by its specific gravity.
3. Presence of characteristic cellular elements in the stained film of the stool.

1. *Presence of Comma-Vibrio in the Film Preparation of the Stool.*—In ordinary text-books on tropical diseases this has been emphasised almost as a constant feature of the disease and vibrios are said to occur in large numbers in the rice-water stools. This view is also held by people in touch with the current literature on the subject. In a review of an article published by Goss (1923), the reviewer observes "this (absence of vibrio in the

where no vibrios were visible, but nevertheless they were cultivated successfully on special culture-media.

For microscopical examination, films were made from fresh samples by crushing a small fragment of mucus between two clear slides and then staining the air-dried film with dilute carbol-fuchsin. This procedure proved more accurate and reliable than the ordinary method of rubbing a small bit of mucus on the slide with a platinum loop. The results arrived at are given below.

Total number of cases examined ..	495
Comma-vibrios present in ..	416
Comma-vibrios absent in ..	79

From the above it would appear that 84 per cent. of the cases investigated showed vibrios in the film.

2. *Presence of Concentration of Blood as shown by its Specific Gravity.*—This was determined by the drop method as recommended by Rogers (1921).

Total number of cases examined ..	496
Number of cases showing the specific gravity to be 1,057 and upwards ..	459
Number of cases showing the specific gravity to be 1,055 and 1,056 ..	29
Number of cases showing the specific gravity to be 1,054 and below ..	8

Thus a definite concentration of blood was noticed in 92 per cent. of the cases. About 6 per cent. of them were practically on the borderline, unless one was prepared to take Rogers' figure 1,054 as that representing the average specific gravity of Indian blood in health. Even then 2 per cent. of the cases failed to show any concentration. Besides, in a mild case where there is no failure of circulation and where absorption of fluid from the stomach is not hampered, this is apt to be a very inconstant feature, and much reliance cannot be put upon it as it indicates only loss of fluid which may occur in other intestinal diseases such as dysentery and ptomaine poisoning.

3. *Presence of Characteristic Cellular Elements in the Stained Film of the Stool.*—Cytological elements in the stool have furnished important clues in the diagnosis of such diseases as amebic and bacillary dysenteries. In cholera where the disease runs a very acute course and toxins of the comma-vibrio exert a specific action on the epithelial cells of the small intestine leading to their necrosis, desquamation and evacuation with the stools, a faithful picture of the morbid changes is obtainable throughout the whole course of the disease. And this can be very easily brought about by merely staining a thin film of the stool made from a small bit of mucus, according to the procedure described under sub-heading No. 1. The cells are usually the altered epithelial cells of the small intestine with badly-stained, nuclei and very little protoplasm

PLATE I.

Degenerated epithelial cells.

Micro-photograph.

Degenerated epithelial cells.

Smear preparation of cholera stool showing degenerated epithelial cells.

small intestine) is such an unusual condition since the stools of cholera patients generally swarm with vibrios." Our experience, however, is not in accord with that of the reviewer or of the text-book writers. During our investigation we often came across cases in the acute stage

round them. They may be few in number but are invariably present. Polynuclear cells are, as a rule, absent (*vide plate*).

Total number of cases examined ..	367
Characteristic cells present ..	359
Characteristic cells absent ..	8

They were present in 98 per cent. of the cases. Where they could not be seen they were either obscured by faecal debris or were disintegrated by putrefactive bacteria in a stale specimen.

CONCLUSIONS.

1. In a total of 495 cholera cases diagnosed bacteriologically comma-vibrios were found microscopically in 84 per cent. of the stool films.
2. In a total of 496 cholera cases 92 per cent. showed definite concentration of blood. In 6 per cent. of them the concentration was indefinite and in 2 per cent. there was no concentration at all.
3. Cytological elements in the cholera stool are constant and characteristic and can be utilised as a reliable index in 98 per cent. of cases.

A NOTE ON THE CULTIVATION OF AN ENTAMOEBA FROM A MONKEY (*MACACUS RHESUS*).

By Assistant Surgeon B. M. DAS GUPTA.

Assistant Professor of Protozoology, School of Tropical Medicine and Hygiene, Calcutta.

On the 9th May, 1925, a monkey which was experimentally infected with *Trypanosoma evansi* in the laboratory, died. The post-mortem was done within four hours of death.

On careful examination of the contents of the cæcum for intestinal protozoa very scanty, sluggishly motile entamoebæ were seen. There was no evidence of ulceration in the cæcum or in any other part of the large gut.

Four sets of culture were made in the following media:—

1. Human blood agar slant, two-thirds of the slant being covered with Locke's solution containing egg albumen in the proportion of one egg to 1 litre.
2. Ordinary nutrient agar slant + defibrinated rabbit's blood put at the bottom of the tube, covered with Locke's solution containing rabbit's serum diluted 1 in 10.
3. Locke's solution + human serum diluted 1 in 8.
4. Row's hæmoglobin medium.

The cultures were incubated at 37°C. for 24 hours. The first two culture tubes showed a few very active entamoebæ containing numerous ingested bacteria. In the fresh state the nucleus was not visible nor could the difference between the ecto and endoplasm be made out.

In an iodine preparation, however, the ring nucleus typical of the genus entamoeba was easily seen. There was no growth in the culture tubes 3 and 4. A better growth was obtained after 48 hours' incubation and some of the entamoebæ in tube 2 were found to contain red blood corpuscles.

Examined on the fourth day the culture showed no entamoebæ (vegetative or encysted) even after prolonged search, there being a heavy growth of bacteria, yeasts and blastocystis.

As the parasites died out so soon a systematic study of their cytological characters was not possible nor could their pathogenicity be tested. However, from the characters noted above, i.e., (i) motility, (ii) character of ecto and endoplasm, (iii) character of nucleus, and (iv) ingestion of red blood corpuscles, I am of opinion that the entamoeba cultivated was *E. mitalli* (Castellani).

It will not be out of place to mention here that the writer, whilst working with Major R. Knowles, I.M.S., has cultivated *Entamoeba histolytica* both from kittens experimentally infected with this entamoeba as well as from the stool of a human case of amoebic dysentery with marked success, using the technique of Boeck and Drbohlár. The kitten and human strains were kept going up to the 32nd and 13th day, respectively, by repeated subinoculation at intervals of 24 or 48 hours.

A Mirror of Hospital Practice.

NOTES ON TWO CASES OF ENCEPHALITIS HÆMORRHAGICA AFTER NOVARSENOBILLON ADMINISTRATION.

By Capt. K. SEN, M.B., Chittagong.

Case No. 1.—Died. R. R. C., aged about 27 years. Onset; on the third afternoon after his second injection of novarsenobillon (dose reported to have been 0.6 gm.), the patient felt unwell and feverish, with severe headache. He went to see his medical attendant, who was away from town. He came back, took some quinine and his usual meal and retired to bed early. At night his headache was intense with high fever (temperature not taken), his speech incoherent and he was delirious. In the early hours of the morning he had epileptiform convulsions and rapidly passed into a state of unconsciousness. The jaws were tightly locked and he passed urine involuntarily.

When I saw him in the morning he was unconscious with temperature 102°F., pulse 120,

respiration rate 40 per minute; blood pressure high; tremor in the muscles of the upper and lower extremities; the jaws alternately locked and relaxed; the deep reflexes absent; the eyes staring; conjunctivæ intensely congested; the pupils contracted and but sluggishly reacting to light. The urine shewed albumin in moderately large amounts.

Treatment.—Rectal enemata were given, together with chloral and bromides rectally every six hours. An icebag was applied to the head and nape of the neck. Lumbar puncture was advised but was strongly objected to by the relatives, as also was venesection. In the afternoon the patient's condition was much the same; temperature 99.8°F ., pulse 90, respiration 24. In the evening a *kaviraj* was called in, and he died at about the 32nd hour after the onset of symptoms.

Case No. 2.—Recovered. A. K. P. of Baraidala, aged 30 years. On the fourth afternoon after his second injection (dose reported to have been 0.6 gm.), was taken ill. His symptoms were practically identical with those of the first case, but there was no fever; temperature 98.6°F ., pulse 108 and of low tension, respiration rate 42, with Cheyne-Stokes breathing.

Treatment was as in the first case, the relatives having refused lumbar puncture and venesection. He recovered partial consciousness in four days and was fully conscious in ten days.

A CASE OF RIGHT-SIDED PLEURAL EFFUSION EXTENDING INTO THE EPIGASTRIUM.

By J. N. SEN, M.B. (Cal.), M.R.C.S. (Eng.), L.R.C.P. (Lond.),

Deputy Chief Medical Officer, Tata Iron and Steel Co., Jamshedpur.

A MAHOMEDAN woman, aged 26 years, married, was admitted to the Jamshedpur (Tata's) hospital on 15th February, 1925, complaining of severe pain and a swelling in the upper part of the abdomen, with difficulty in breathing and severe paroxysmal dry cough. The cough began after the onset of the pain. She could not say definitely whether the pain or the swelling began first.

Previous History.—She says she never had any chest or abdominal trouble previous to this. She was leading a healthy life up to the onset of the present illness. She has had no children and there was no menstrual trouble, her periods having been regular. She had no venereal disease, neither had her husband had any to the best of her knowledge.

Present Condition.—She looked rather thin and anæmic. The conjunctivæ were pale and there was no jaundice. The face looked anxious

and there was dyspnoea. Her sleep was disturbed owing to the severe pain in the epigastrium. The pulse was 120 and of low tension. Respiration was difficult and 32. The temperature was subnormal (96°F). On inspection the chest looked more full on the right side and its mobility was impaired. There was no oedema of the chest wall. On percussion the right side of the chest was woodenly dull from below the clavicle right down to the costal arch.

On auscultation, the breath sounds were markedly diminished and egophony was heard at the upper part of the right chest.

Heart.—The apex beat was outside the left nipple line, otherwise the heart was normal.

Abdomen.—There was a round, soft swelling of cystic type of the size of a small bael fruit in the epigastric region. It was ill-defined and dull, and the dullness merged into that of the right side of the chest. No thrill could be elicited over the tumour. It was tender and painful. Over the tumour there were marks of the counter-irritation which these Indian women employ for the relief of pain. The spleen was enlarged. The liver margin could not be felt owing to the pain, but the abdomen was tender along the costal margin on the right side of the tumour. The abdomen was normal elsewhere. The bowels were constipated, not having moved for the last three days. The urine was normal, no albumen being found, but the quantity of urine, according to her statement, was diminished.

The blood was not examined and an x-ray photograph could not be taken owing to lack of apparatus.

Diagnosis.—There was no doubt about the collection of fluid in the right side of the chest. The difficulty in diagnosis was the nature of the lump in the epigastric region. It might have been a hydatid cyst, an enlarged gall bladder, a subphrenic abscess, a cyst of the lesser omentum, or a pancreatic cyst. As she had great dyspnoea which was to a great extent due to the collection of fluid in the pleural cavity it was decided to aspirate her first. This was done on 16th February, 1925. Two pints of straw-coloured serous fluid came out. During aspiration it seemed that the swelling in the epigastric region went down a little. She then immediately began to cough violently and the cannula was withdrawn. After aspiration she seemed a little better, the dyspnoea also seemed less. The next day she felt better and said the cough was less, but the epigastric swelling looked just as big as before the aspiration. This apparent diminution of the swelling during aspiration gave me the clue that the swelling in the epigastrium might be an extension of the contained fluid within the pleural sac. On 20th February, 1925, she was again aspirated and three pints of fluid were taken out, and with this the epigastric swelling went down markedly to a great extent and she felt very much better.

Next day the swelling was entirely gone and with it the pain and tenderness as well. From this time onwards she felt better every day and was discharged on 2nd March, 1925.

Remarks.—The interest of the case lies in the fact that the patient came to hospital for the relief of pain and swelling in the *epigastric* region. During physical examination effusion was detected in the right side of the chest and hence it was aspirated. It never struck me that the swelling in the epigastric region had any connection with the pleural effusion. It must have made its way through the diaphragm where it is deficient in muscular tissue, by the side of the ensiform cartilage. The pain was probably due to some pleuritis and local peritonitis.

My thanks are due to my assistants, Drs. K. B. Chatterjee and S. N. Sen, for compiling these notes for me.

A CASE OF CHOLERAIC DYSENTERY.

By P. K. KURUP, L.M.P., Naduvannur, Malabar.

The patient, a male, aged 22, Abbagi by name, was admitted into the emergency ward of the L. F. Dispensary, Avanashi, Coimbatore district, at 7-45 A.M. on 14th November, 1923, with dysentery and vomiting.

He belonged to a place 7 miles off and he had no relatives to take care of him. He was a tailor and a fellow tailor brought him to my dispensary for treatment. On admission the patient appeared to be a typical case of cholera. The cheeks were hollowed with prominent zygoma, the nose pinched and the eyes sunken and the skin of the fingers shrivelled. He was passing profuse and red-coloured watery stools. There was complete suppression of urine. The respiration was rapid. He could not talk but could only whisper. The pulse was scarcely perceptible. The temperature was sub-normal, 94°F. He was restless and tossing about, complaining of intense thirst in a whispering manner and making signs for water. He whispered and showed with his hands that he had some pain in the chest.

To my mind the case appeared to be a typical one of cholera in the "algid stage," but the colour of the stools was evidence strongly against this diagnosis, though blood may be found in the stools of cholera patients at a certain stage in some cases.

I treated him for collapse. Potassium permanganate solution and pills (2 gr.) every 15 minutes for two hours were given and afterwards the pills were repeated every half an hour. Chlorodyne and Mistura Pro-diarrhoea to promote the reaction were used. By 11 A.M. the patient became a little better and his pulse improved; and the number of motions was less. Towards evening, he had 4 motions which were very small, containing blood and slime. I suspected some poisoning in the beginning, but ex-

cluded that since he gave strong negative evidence. I suspected poisoning by *kalli* fruit which the people of those parts eat very indiscriminately. But even that was excluded by his history. The only history was that he was suddenly attacked with purging and vomiting at 10 A.M. on 13th November, 1923.

Some ten days prior to the incident the place whence the patient came, was declared to be infected with cholera and there were three cases.

The patient was given strychnine injections and saline and atropine, but to no avail. By evening the patient said that he felt better but I did not find any improvement in his condition. He died at about 12 P.M. on 14th November, 1923.

One peculiar phenomenon, I observed throughout the patient's illness, was that both his eyes were much injected from the beginning to the end. A post-mortem on the body of the deceased was not available. I diagnosed the case as "Choleraic dysentery."

[*Note.*—Possibly a fulminating case of Shiga bacillus infection.—*Error, I. M. G.*]

A CASE FOR DIAGNOSIS.

By N. CHATTERJEE, M.B.,
Domjore, District Howrah.

I WAS called in to see a patient in the middle of the night, with the following symptoms:—

Pain all over the body; retention of urine, flatus and fæces for 36 hours; but no fever.

On the 5th March, 1925, he had come down from Calcutta and began to have vomiting and pain in the umbilical region. He was treated by a local doctor and the vomiting ceased, but the pain continued and settled in the left side. The patient was a boy of some 15 years, with an anxious look, but fully conscious; respiration was of thoracic type; the abdomen soft but distended; there was no fever; the pulse rate was 105, and the respiration rate 45. There was marked tenderness in the hypogastrium and left inguinal region and a tympanitic note on percussion of the abdomen. Intestinal peristalsis was not in evidence.

A soft rubber catheter was passed, but only a few drops of urine were evacuated, whilst a soap and water enema was without result. There appeared to be nothing wrong with the heart, and the patient was kept under observation till the next morning.

The condition then was still the same, except that the pulse rate was now 115, but there was still no fever. The relatives refused to have the patient removed to hospital. Eight hours later he developed subdermal hæmorrhages under the skin of both legs and the abdomen, and died some ten hours later. There was no fever throughout and no prodromal rash. He was vaccinated a year previously.

AN INTERESTING CASE OF DIABETES IN COMBINATION WITH A CONDITION OF LOW KIDNEY-THRESHOLD.

By Dr. P. V. GHARPURE, M.D. (Bom.),

Grant Medical College Bombay.

MR. G. N. K., an adult male, aged 40, a strict vegetarian and gymnast by profession, had suffered from (?) syphilis and gonorrhœa about 8 years ago, and had been treated for both on modern lines. He suffered from increased appetite, thirst and progressive weakness during the past few years, and for these complaints he consulted me.

Having found sugar in his urine on my first seeing him, I got him admitted into hospital for insulin treatment.

The results of my investigation are as follows:—

5th February, 1925.—The patient was allowed his usual diet and a 24 hours' sample of his urine showed the sugar to be 7.25 per cent.

6th February, 1925.—Six hours after his principal meal his blood-sugar was estimated; it was found to be above 0.30 per cent. and his urine showed sugar. This estimation was carried out only as a preliminary step.

7th February, 1925.—Complete starvation. (He was allowed only water.) At the end of 24 hours his urine became sugar-free, but he began to feel uneasy, began to get headache, sudden weakness and hunger, which meant hypoglycemia. I allowed him a small quantity of boiled rice and he felt relieved. The urine voided at night showed a trace of sugar. Starvation was continued.

9th February, 1925.—Sugar tolerance test:—

Blood-sugar estimation—McLean's method.

9.25 a.m. .. 0.86 per cent.

The urine was sugar-free. Immediately after taking the blood he was given 50 gms. of glucose.

9.55 a.m.	..	0.100 per cent.
10.25 a.m.	..	0.112 per cent.
10.55 a.m.	..	0.112 per cent.
11.25 a.m.	..	0.112 per cent.
11.55 a.m.	..	0.118 per cent.
12.25 p.m.	..	0.118 per cent.
12.55 p.m.	..	0.118 per cent.

At this stage his urine showed sugar.

From this date onwards he was allowed full diet, as I thought that his glycosuria was due to his renal failure, all the same suspecting diabetes.

22nd February, 1925.—12.30 (one hour after food) 0.231 per cent.

Urine showed sugar.

2 p.m. (2½ hours after food) 0.225 per cent.

As the blood-sugar was keeping high for such a long time no further estimation was done.

Evidently the percentage of blood-sugar above the kidney-threshold and its maintenance at a height for nearly 3 hours shewed the case to be one of confirmed diabetes.

CONCLUSIONS.

1. The patient is a diabetic, and has a lowered kidney-threshold.

2. His mechanism of keeping blood-sugar at about normal is faulty.

3. His blood-sugar falls below normal too rapidly by starvation and he actually shows signs of hypoglycemia.

4. It is not possible to say how far a dose of insulin before his meal would reduce his blood-sugar, and I thought it might prove harmful to test it.

5. The case appeared to me to be unfit for insulin.

6. No reference to such a case with some guide to deal with it could be found.

A CASE OF KALA-AZAR WITH TRANSPOSITION OF THE VISCERA.

By K. N. CHATTERJEE, M.B.,

Chinsura, Howrah District.

A VERY advanced case of kala-azar is under my treatment. The patient is a Bengali male child, aged about 8 years, and is an inhabitant of the Howrah District. His blood was examined by a specialist, and several injections were given to him, including "urea-stibamine," but no appreciable improvement took place.

The first day when I tried to palpate the boy's liver, I was surprised not to find the organ in its place, but felt instead the shape and consistency of a huge spleen hanging directly from beneath the right costal arch and extending below as far as the right iliac fossa. I then began to search for the liver and found the organ was lying on the left side, as far as the middle line, entirely occupying the left hypogastric region, and extending below as far as the umbilicus. The soft and sharp margin of the organ together with the notch between the two lobes were very distinctly felt. The position of the stomach could not be ascertained owing to the entire upper abdomen being covered by the enormous liver and spleen. The heart was also on the right side.

The case was shown to Lieutenant-Colonel D. Basu, I.M.S. (ret'd.), who confirmed my findings.

The patient's father is dead, but neither his mother nor any other known member of the family has transposed viscera.

The child is now well on the way to recovery after further injections of sodium antimonyl tartrate.

Indian Medical Gazette.

JULY.

THE BENGAL AYURVEDIC AND UNANI COMMITTEES.

AN ANTICIPATION OF THEIR REPORTS.

MORE than three years ago, two Committees were appointed by the Government of Bengal to "consider and report what practical steps can be taken for the restoration and development of the Ayurvedic and Unani systems of treatment with special reference to the question of teaching these systems under proper supervision and control."

We understand that the reports of these Committees are already in the hands of the Government of Bengal and may shortly be published.

Each of the two Committees was composed of:—(a) several practitioners of the system of medicine which was under consideration; (b) several practitioners of scientific medicine; and (c) some representative laymen. We hope shortly to be able to comment on the reports themselves, but in view of the interest of the subject we have asked ourselves what kind of reports might have been expected to emanate from the two Committees?

The following is an attempt to answer the question, but we may as well admit at once that the anticipation which we produce is widely different from the reality. None the less here is what we should have expected each of the reports to be like.

REPORT.

The Committee at the very first meeting discovered that it was impossible to expect that any report could be submitted which would comply with the terms of reference as laid down by Government. The points of view of the various sections of the Committee are briefly stated for the information of Government.

NOTE BY THE PRACTITIONERS OF THE ANCIENT SYSTEMS.

The Ayurvedic (or Unani as the case may be) practitioners and members of the Committee are conscious of the good intentions of Government in taking steps to encourage the ancient systems of medicine and are duly grateful for this expression of sympathy, but they cannot fail to record their opinion that an unintentional slight has been cast on the practitioners of the system.

With all respect to Government, we must point out that the followers of the Allopathic system, who have been appointed to the Committee, have no intimate knowledge of our systems and, however well-intentioned they may be towards that

system they cannot be possessed of the qualifications which are essential for working out a scheme for its restoration.

Even in the improbable event of their learning enough of our system in a short time to enable them to co-operate with us in an intelligent manner in preparing a united report, we feel that any report which might be agreed on by by them and us would be looked on with natural suspicion and mistrust by the main body of the practitioners of our system.

For this reason it is not likely that such unanimity would prevail among the practitioners of the system that Government would be justified in taking action on the report.

We beg also to point out that although some of us admit that our system might derive benefit by adopting some of the methods which are in use among Allopathic practitioners, the majority of our practitioners regard our system as complete and self-sufficient so that they would resent the suggestion that it can be restored and improved by the help of Allopathic medical men. Had Government been pleased to appoint a Committee consisting of representative practitioners of our ancient system, we should have been glad to show how best the system could be encouraged and fostered so that it might take its proper place as the national and official system of the Province. After years of official neglect and discouragement our system is still accepted by large numbers of the population, and the fact that it is still so popular in spite of all difficulties is enough to show that it would be capable of supplying the needs of the people if it were accorded the same degree of recognition and support as the official system.

We would recommend to Government the adoption of the policy which has been followed by the Government of the United Provinces, in which a Committee consisting of practitioners of the indigenous system and of laymen who are sympathetic to the system has been appointed to recommend steps for the improvement of the Unani or Tibbi system.

NOTE BY THE PRACTITIONERS OF SCIENTIFIC MEDICINE.

After an amicable exchange of views with the Ayurvedic (or Unani) medical members of the Committee we are forced to agree with them that no good results can follow from an attempt to comply with the terms of reference of Government. The note submitted by the practitioners of the ancient system states the reasons for this opinion.

We desire, however, to place before Government some points for their consideration.

(1) We think that the first thing to be considered is whether it is desirable for Government to take steps for the restoration and improvement of the ancient systems.

(2) The development of various systems of medicine in the world generally has been a natural

one and has not resulted from the action of governments.

All governments have made use of the knowledge that has been acquired by medical men for the protection of the health of the people and so public health departments have sprung up. Some governments, notably the Government of India, have given state aid, to medical relief, medical education, and medical research, and these governments have adopted scientific medicine as the system which has received official recognition and support.

(3) The action of the Government of India in subsidizing scientific medicine has not resulted from racial, national or religious prejudice. Every progressive country in the world has adopted scientific medicine rather than the traditional systems of the country, because all the educated classes of each country have by common consent regarded scientific medicine as the only system which is capable of meeting the needs of the people.

We may point out that the East Indian Company believed that the best way of bringing medical relief to India was by adopting the prevailing indigenous system: the attempt to develop the indigenous systems was a failure, because the educated classes turned to scientific medicine, and the foundation of the Calcutta Medical College was the natural result of the inclinations of the Indian community.

(4) We must protest against the appellation "Allopathic practitioners." We do not adhere to any traditions whatever; our system of medicine is not "Allopathic," it is not "European," it is not "Western," it is not perfect nor self-sufficient. It represents the stage of progress that has been reached by scientific workers in every progressive country of the world. While it is not completely scientific, as our knowledge is far from perfect, it deserves the name of "International Scientific Medicine" in that its aim is scientific accuracy and completeness, and in that it is entirely free from national or local prejudices of any kind.

It is a popular fallacy that scientific medicine is one of several systems which are competing for the suffrages of the people; we admit that some practitioners call themselves Allopathic physicians and suggest to the people that their system is complete and all-sufficing, in the same way as many Ayurvedic and Unani physicians claim that their systems are complete and superior to all others.

The true follower of scientific medicine admits his fallibility and imperfection and for this reason he commands the respect and confidence of the educated community.

He justly claims that scientific medicine is the only true system, because it accepts and employs everything that has been shown to be useful, from whatever source it be derived. He holds that all other systems are doomed to final extinction in India and in every country of the world

for the very reason that they claim to be self-sufficient and complete. When they cease to make this claim and when they recognise that the only true system is that which takes everything that is best from every source, they will automatically become merged in scientific medicine. It would, therefore, appear to be a retrograde step to attempt to restore any traditional system of medicine.

(5) We admit that our knowledge of the ancient systems is not sufficient to justify us in pronouncing judgment on them in detail: the systems may have valuable items of knowledge which we have hitherto failed to secure, for this reason we would recommend to Government the institution of an enquiry into the various ancient systems, with a view to the publication of those methods of diagnosis and treatment which are claimed to have special value and which may not be available to the world at present.

A study of the ancient books and of any modern text-books which give an account of the methods employed by practitioners of the system will be of great interest and will form a necessary prelude to the state recognition of the systems.

We cannot recommend the formation of schools or colleges which will teach matters of which we are ignorant. Our system is universally accepted all the world over, it has been clearly and fully published for all to read and to judge. No system should receive state aid and recognition until it has been examined. We, therefore, suggest that the practitioners of the ancient systems should be given the fullest facilities for stating their case. Let them select representatives, who will be subsidized by Government, for the production of a clear and intelligible account of the valuable features of their systems and who will show reasons why it is in the public interest to restore the ancient systems. They should be asked to prepare a scheme by which public health and medical relief can be promoted on lines which are not now available to international medicine as practised by medical men and public health workers all over the civilized world.

If, for political reasons, Government should decide to inaugurate schools of teaching of the ancient systems, without reference to the inherent desirability of such a step, we would respectfully beg to be excused from taking any part in the organization of these schools. If we were to meddle in the affairs of the indigenous systems our action would give rise to suspicion and mistrust. We should be suspected of an insidious attempt to proselytize the practitioners of the ancient systems, and our action would not command the support of scientific medical men.

NOTE BY THE LAY MEMBERS OF THE COMMITTEES.

We regret that we are not in a position to pass judgment on the views expressed by our medical colleagues.

We have great sympathy with the aspirations of the practitioners of the ancient systems of medicine, but in view of the statements made by the practitioners of scientific medicine, we feel that Government would act wisely in adopting their suggestion that facilities should be afforded to the practitioners of the ancient systems to give clear expositions of their causes.

The public will then be in a position to judge whether the claim for the restoration and teaching of the ancient systems is justified and whether its acceptance is in the interests of the people.

It may be that there is something in each of the ancient systems which makes it specially suited to the climatic and individual constitutional conditions which prevail in India.

If so it is important that we should be in possession of the facts. Great claims have been made by the practitioners of the ancient systems, indeed, these are much greater than those made by scientific medical men. On the other hand we cannot ignore the fact that scientific medicine has been accepted by the great majority of the intelligent and educated classes in every country in the world, and, therefore, we feel that we cannot accept the claims of the practitioners of the ancient systems without full investigation.

Such is the report that might have been expected from each of the Committees, we shall shortly see to what extent it corresponds with the actual reports which have been presented to Government.

SPECIAL ARTICLES.

"THE MEDICAL ASPECTS OF CHEMICAL WARFARE."*

It is pretty certain that there will be a "next war," and it is equally certain that it will be fought with gas, unless some other and more effective form of frightfulness has been discovered in the meantime. Hence the importance of this very complete, authoritative and wonderfully-illustrated exposition of the subject. In brief, the book is one which is essential to all military medical officers. Whatever may be the popular belief as to the barbarousness of using gas, it has come to stay; indeed it may be the decisive weapon of future wars. Colonel Vedder claims that gas can be made far more humane than rifle or artillery fire, and the terrible photograph on p. xii of his preface—showing complete destruction of the face from a bullet wound, without death having ensued—certainly goes far to support his contention. Also gas is often far more efficacious than artillery: in the first German gas attack at Ypres on April 22nd, 1915,—of which a very striking aeroplane photograph is given in the frontispiece,—180 tons of chlorine were liberated on a front of 6 kilometres: the gas attack lasted for five minutes; the British lost 5,000 killed and many times that number of casualties: had the Germans known it, they could have walked through

to the Channel ports. In the next war it is quite likely that entire cities may be wiped out by intensive gas attacks from the air. At the Hague Congress of 1899 all the powers present (except the U. S. A.) pledged themselves not to use poisonous or suffocating gases; the Germans not only violated this pledge in 1915, they committed the even greater crime of using their new weapon foolishly; to-day sees every first-class military power absorbed in the study of the gas problem.

Following an introductory chapter on the history of chemical warfare, come chapters which deal fully with the physics and elementary chemistry of the subject, the very important subject of meteorology in relation to it being next discussed.

Turning first to smoke clouds, two types are in use: (1) screening smokes which interfere with visibility: and (2) toxic smokes which are poisonous or irritant. If a large volume of smoke is emitted from a single source, it spreads in a cone-shaped manner, and continues to spread at a uniform rate for a considerable distance, the angle of spread being from 10° to 15° on each side of the axis of the wind. Wind velocities of 10 to 12 miles an hour are those most suitable for the use of gases and smoke. As the air close to the ground moves more slowly than the air above it, the upper surface of the cloud is blown forward faster than its lower surface, and hence the weight of such a cloud is limited. Humidity is of importance; thus phosgene and lewisite are hydrolysed by heavy rain, whereas mustard gas is hardly affected.

The chief types of gas used during the war were:—(1) pulmonary irritants, such as chlorine, phosgene and chlorpicrin; (2) vesicants, such as mustard gas; (3) lachrymators, such as chlor-aceto-phenone and brom-benzyi-cyanide; (4) irritants causing sneezing and irritation of mucous membranes; (5) direct poisons, such as hydrocyanic acid; and finally (6) gases which act by interfering with the respiratory properties of the blood.

Turning to the pulmonary irritants, chlorine is now of only historical interest. It was the first gas used by the Germans, but can be easily guarded against. Even at a 1 in 10,000 dilution it brings on coughing and a sense of suffocation. Death occurs either immediately, or within 24 hours, and the post-mortem findings are acute tracheitis and bronchitis with sloughing of the mucous membranes; acute congestion and œdema of the entire respiratory tract, acute dilatation of the heart, and passive congestion of the abdominal viscera. Apparent improvement may be followed by septic infection and death from broncho-pneumonia. Phosgene — CO Cl_2 — is far less irritant and far more deadly. Even in high concentrations, the patients may shew no early signs of irritation: thus field hospital patients may leave their beds to visit the latrine, and a moment after returning may be taken ill with progressive and fatal dyspnoea. A good example is that of a chemist accidentally gassed with phosgene in a laboratory at 1 p.m. Until 5 p.m. he was quite comfortable and free from symptoms: coughing commenced at 5-30 p.m. and he died at 6-50 p.m. Progressive pulmonary œdema is the dominant symptom, and patients may die in blue asphyxia with cough and rapid respiration, or in grey asphyxia with but little cough or expectoration, shallow rapid respiration, and heart failure. Most of the fatal cases die within 24 hours of being gassed; very few die after the third day. The acute œdema of the lungs is due to local injury to the alveolar capillaries, and as the œdema fluid is derived from the blood, there is great thickening of the blood, the erythrocyte count rising as high as 9,000,000 per c.mm. Anoxemia is marked, and all the conditions present overload the right side of the heart.

Chlorpicrin is more irritant than phosgene,—lachrymation being the first warning of its use, followed by nausea and vomiting. The patient appears to age rapidly and there may be acute nephritis. The bronchial damage is less severe than with chlorine, but there is extreme œdema and congestion of the lungs.

* "The Medical Aspects of Chemical Warfare," by Lieut.-Col. E. B. Vedder, M.C., U. S. A. Baltimore: Williams & Wilkins Co., 1925. English Agents: Baillière, Tindall & Cox, London. Demy 8vo., pp. 327. plus xvi; 52 illustrations. Price 32s. 6d.

In the treatment of gassing from pulmonary irritants, diagnosis is the first difficulty, especially with phosgene cases: 24 hours' observation or less, however, will soon shew whether the patient has been gassed or not. The clothing should be loosened and the patient kept absolutely at rest. In hospital venesection and the administration of oxygen are the chief lines of treatment. At the height of the attack from 500 to 700 c.c. of blood may have to be withdrawn. Injections of urease, a ferment which acts on the blood, liberating ammonia which will neutralise the acid effects of the irritant gas are also useful; 1 c.c. of a 10 per cent. solution being given intravenously per 10 kilos. or in all about 7 c.c. for a man of average weight. Emetine subcutaneously also serves to reduce the pulmonary oedema. In phosgene poisoning intravenous injection of a solution composed of 25 per cent. gum arabic with 25 per cent. glucose combats the concentration of the blood. Oxygen must be administered, best through a nasal catheter, continuously and over a long period. Cardiac stimulants and fluids freely to relieve thirst are also indicated. Patients who have recovered from the acute pulmonary oedema must be carefully watched and nursed to prevent secondary septic pneumonia. Of 4,575 cases gassed with irritant gases, the average stay in hospital was six weeks, and most of the patients were able to return to duty in from ten to nineteen weeks. In a very small proportion of cases the gassed individual becomes unfit; such cases being grouped as cases with symptoms of irritable heart, cases with nocturnal spasmodic dyspnoea, and cases of mixed type. Graduated exercises are the best line for the first group, and oxygen treatment for the second.

Turning to the vesicant gases, mustard gas—yperrite or yellow cross—was the first to be used against the British. It is a heavy oily liquid, was used in shells, and is ten times as lethal as chlorine. It was the most effective chemical agent used during the war and produced more casualties than did any other type of gas. Among the British gas casualties in France it is estimated that 80 per cent. were due to yellow cross shells (mustard), 10 per cent. to blue cross shell (arsenicals), and 10 per cent. to green cross shell (pulmonary irritants). Mustard is toxic in concentrations which cannot be detected by the sense of smell; it is a heavy and persistent gas, and breaks down morale, since men do not know with certainty that they can eat, drink, sleep or even sit down with certainty. In a severe case dying within 48 hours, burns of all degrees from erythema to extreme blistering may be found on various parts of the body as the gas readily penetrates clothing. There is advanced conjunctivitis, the pharynx and posterior third of the tongue are oedematous and may shew necrosis. The trachea and bronchi are lined with diphtheritic casts, and the lungs engorged. Clinically we have mild cases with chronic irritation of the airways and lungs,—some of which may develop severe general reaction, septic involvement of the lungs and may end fatally; intermediate cases with extensive burns, aphonia, severe abdominal colic, continuous cough and acute conjunctivitis and nasal catarrh, with fever; and severe cases with severe ulceration and disturbance of the central nervous system. Different individuals shew the most surprising difference in reaction to mustard gas; slight exposure will lay one man out prostrate with oedema, itching, and cough; whilst a second exposed to the same concentration may shew no symptoms. A sensitivity test to the skin can be relied upon to eliminate the former class, which forms some 2 per cent. or less; whilst at least 25 per cent. of men are very resistant.

In the first aid treatment of mustard poisoning, the first step is to remove the gas from the skin, which it penetrates very rapidly. Soap and water are not very effective; but sponging the exposed parts with kerosene on a clean cloth for 30 minutes is very efficient, followed by green soap and hot water. If these solvents are not available, aqueous chloride of lime solution or Dakin's solution should be used. Immediately on ad-

mission to hospital, all clothes should be removed, and the patients should pass through a shower bath before admission to the ward,—otherwise they may carry mustard with them into the ward. Particular attention must be paid to the hair, which becomes saturated with the gas. The acute conjunctivitis must be treated with the usual measures, and local application of pure liquid paraffin is soothing and protective. The nasal and pharyngeal mucosae must be thoroughly cleansed with bicarbonate solution; whilst menthol inhalations from steam,—menthol 10 grs., tinct. benzoinæ co. 30 c.c. with hot water—are very useful. In order to prevent septic infection of the denuded bronchi a mask must be applied with menthol, chloroform, eucalyptus, etc. The skin must receive continuous and thorough treatment; ointments are useless but Dakin's solution, a surgical vanishing cream containing chloramine-T, and warm bicarbonate baths are useful measures. Benzyl alcohol, 100 parts; ethyl alcohol, 96 parts, with glycerine 4 parts is a useful lotion to relieve itching.

Lewisite was a gas introduced in 1918, but not actually used during the war. It is chlor-vinyl-dichlor-arsine, and is a heavy, oily liquid. It is a stronger vesicant than mustard and also a powerful respiratory irritant, and may possibly be employed in the form of liquid sprays from aeroplanes. With regard to treatment, fortunately the gas is easily hydrolysed. All burns with liquid lewisite should be instantly treated with a 5 per cent. solution of caustic soda, which again must be itself removed with water as it is irritant also. On admission to hospital the best line of treatment would be immediate excision of the burnt areas if possible. For vapour burns a ferric hydrate paste containing colloidal ferric hydrate is advised.

Lachrymatory gas shells were first used by the Germans in April 1915, and were used to a considerable extent throughout the subsequent years of the war to harass troops. Deaths due to these gases were very rare. Xylol bromide was first used, followed by brom-benzyl-cyanide and later chlor-aceto-phenone, which proved the most efficient of all. Brom-benzyl-cyanide is very stable, and an area of ground sprayed with it will still retain irritant properties 30 days later, in spite of weather conditions. On the other hand it has the serious disadvantage of corroding steel and all metals, and if fired in a shell it has to be put into a porcelain container. It is soluble in carbon tetrachloride, and an alcoholic solution of sodium hydrate can be subsequently used. Of the lachrymators, however, the one above all others is chlor-aceto-phenone; this is solid under ordinary conditions, but has a low vapour pressure; it is exceedingly stable and is not affected by metals; it may even be mixed with T.N.T. explosive. Further it is cheap to manufacture and causes lachrymation in a concentration of only 0.0003 mgm. per litre. It was extensively used in hand and rifle grenades. In addition to severe lachrymation slight inflammation of the skin may be produced. In strong concentrations men are blinded and unable to open their eyes for several minutes. A solution of sodium bicarbonate for washing out the eyes is the only measure of treatment necessary, whilst an efficient mask is an absolute protective.

Early attention was paid during the war to the possibility of using the very poisonous arsenical gases. Arsenic itself,—AsH₃—is too unstable and too inflammable to use, but the Germans used its derivative diphenyl-chlor-arsine in their blue cross shell. The Germans hoped that when this gas was used in a shell, the burst of the shell would set free a finely-divided cloud of particles which would be fine enough to penetrate the gas mask, cause violent irritation of the nose and throat, nausea and vomiting; this would compel the men to remove their masks, whereupon ether and more lethal gases would be used. As a rule, however, in actual experience it was found that the particles did not penetrate the masks used by the Allies. In some of the German shell dumps as many as 30 per cent. of the shells were blue cross, and captured orders by Ludendorff as late as July 1918, shewed that he expected very great

effects from it. Actually the substance can be much better used as a smoke spray from burning candles of it and "D.M."—diphenyl-amine-chlor-arsine—is even more efficacious. With a slow wind a cloud produced from 500 candles of D.M. liberated on a front of 500 yards produced vomiting among unprotected subjects placed three miles away, whilst it was still irritating six miles away.

Whilst these irritant smokes are not very lethal, they cause very considerable temporary disability. Intense pain in the nose and throat, tingling and smarting of the face, acute lachrymation, a copious running at the nose, nausea, sometimes vomiting and intense headache are the chief symptoms. Giddiness usually occurred and in some cases unconsciousness. Intense mental distress, however, is the chief symptom with these poisons; even mildly-gassed patients are a picture of misery, whilst severely-gassed persons may lose all mental control, commit suicide or suffer from delusions. Paresthesias also were not uncommon. The vast majority, however, were ill for only a few hours. The treatment consists in rest, fresh air, removal of contaminated clothing, washing the nose and throat with boric acid solution or saline, and an inhalation containing alcohol, chloroform, ether and a trace of ammonia; with phenacetin for the headache. An interesting point about the use of these gases is the poisoning of water holes by them, and casualties occurred from using such poisoned water.

Of miscellaneous gases, prussic acid was not used by the Germans but was tried by the Allies. It was found impossible to obtain lethal concentrations under field conditions. Carbon monoxide was not used as a poison but was a frequent source of poisoning in shelled dug-outs, exploding mines, and closed spaces. Phosphorus bombs were but little used; on bursting they scatter burning lumps of phosphorus around, and the element will still continue to burn after it has penetrated the skin if air reaches it. Thermite bombs of ferric oxide plus powdered aluminium, when they burst, produce a temperature of about $3,000^{\circ}\text{C}.$; this melts the iron, and molten iron is thus scattered about, severe burns resulting.

Chapter 12 deals with individual protection against gas, and first details the evolution of the various protective masks adopted by the different Allies. The present American type of mask is the Mark 3, 1919 canister. Essentials for a good mask are that it must have a high rate of absorption, as in rapid breathing the gas may only be in contact with the absorbent for one-tenth of a second; secondly the absorbent must be able to absorb and hold large quantities of gas per unit weight of material used; thirdly its breathing resistance must be low. The actual canister used is a tin box with two holes for inspiration and one for expiration, each protected by a rubber valve. The corrugated tube—corrugated to prevent its kinking—is attached at one end to the nozzle and at the other end to the face piece. The face piece is made of a special rubber compound, whose outer surface is covered with stockinet, fits so closely to the face by an elastic harness which fits around the head that no outside air can be breathed, and has glass plates in metal frames opposite the eyes. An aluminium tube is inserted in the front of the face piece and has two passages; the upper for the entrance of purified air from the canister, the lower for exit of respired air. The mask is made in five different sizes. The mask is contained in a canvas satchel held in place by webbing straps, whilst the canister is held in the rear of the satchel. The mask weighs 5 lbs. 2 ozs., is simple in construction, and very durable.

The best gas absorbent is charcoal, and the absorbent used in this mask is a mixture of 60 per cent. activated charcoal with 40 per cent. soda-lime. The charcoal is heated in a kiln in the presence of water vapour to a temperature of $850^{\circ}\text{C}.$ for 4 hours; this removes all volatile hydrocarbons from the fine capillaries of the

charcoal, leaving in each granule an enormous capillary bed for gas absorption.

Details for training and gas mask drill follow, illustrated by very clear and numerous photographs; instructions for mask inspection drill, together with an account of a special mask for wear when the face or head is wounded. A further interesting novelty is "Impregnite" underwear, so treated as to be capable of neutralising mustard gas for several hundred hours under field conditions.

Chapter 13 deals with collective protection. Here there are several factors to be considered; not the least the study of local meteorological conditions favourable or unfavourable to the use of different gases. Most gas attacks take place at night, when meteorological conditions are usually more favourable than in the daytime, and when the element of surprise among sleeping men will be greater. Gas sentries should be specially trained. Gas-proof shelters can be constructed in one of two ways; either an air-tight construction is used, all openings being made impervious to gas; or a positive pressure can be maintained inside the shelter by means of air pumped in from the outside through a special canister which removes the gas. Gas-proof shelters should have double doors, the two doors being if possible ten feet apart. A roll blanket door held down by slats is usually fairly efficient. In actual practice gas-proof shelters are not so efficient as they might be expected to be; in the first place they are of semi-permanent construction; in the second, gas is carried into them in the clothing of persons using them. In removing gas from a dug-out or shelter, a fire will create a good draught, and chloride of lime should be used freely, especially after a mustard attack. Clothes saturated with mustard gas should be boiled for 2 to 3 hours, or may be treated with an alkaline bath. Mobile bathing units, 2 units per division, are essential, each equipped with a 1,200 gallon tank and devices for heating water and generating steam. Supplies should be protected against gas, as gas affects many of them as well as men. Food must be kept protected especially; also metallic and surgical instruments.

All medical officers should be trained in the measures to be taken against different forms of gas attack. Patients gassed with pulmonary irritants should be removed immediately before serious oedema has had time to set in; mustard gas cases should not use the ordinary ambulance, as they will infect them. Most of such cases, after first aid treatment to burns, etc., are capable of walking back to the collecting station. The collecting stations in question should be for gas cases only. At the collecting stations many cases which are doubtful should be retained for 24 hours to see whether they are really gassed or are malingering. A mobile bathing unit is an essential element of the gas collecting station. Finally, at the gas hospital centre for each area trivial cases should be detained, as they will soon be ready to return to the front; cases severely gassed by mustard should be evacuated as their treatment will occupy months; phosgene cases will have either died or will be on the road to recovery within 48 hours; but if recovering after that period should be evacuated lying down to convalescent camps. Finally, it should be noted that gas casualties diminish when there is rapid advance or retreat, and tend to become most numerous in stationary warfare or in heavy fighting.

Turning to the ultimate results of gas poisoning, the deaths among 1,80,983 British gas casualties numbered 6,062, or only some 3.4 per cent. for the whole period 1915 to 1918. Gas poisoning was responsible for only some 2 per cent. of pensionable disabilities, 35 per cent. being caused by wounds, and 63 per cent. by disease. About 88 per cent. of gas cases received no permanent injury. In the remainder the average degree of disablement was only some 20 per cent. There is no real evidence that gassing increases the liability to tuberculosis; on the contrary, so far as the evidence goes, men who have been gassed suffer less from tuberculosis than normal individuals under the same circumstances.

Many of the so-called chronic gas poisoning cases were cases rather of war neurasthenia; but few of those who drew a pension would ever admit a subsequent improvement or cure.

Chapter 16, on naval medical aspects of chemical warfare, is by Lieutenant Commander D. C. Walton, M.C., U. S. Navy, who points out how ancient is the use of poisonous gases in warfare; the classical "Greek fire" having been used by the Greeks for some 500 years, whilst quicklime has frequently been used in naval warfare. Gas was not actually used in naval warfare during the Great War, except from land batteries during the attack on the Mole at Zeebrugge, in 1918. Temporary lung irritants, vesicants, lachrymators and sensory irritants are not likely to be used in naval warfare during a fleet action; "practically all gases used at sea would be of a persistent nature, and only those which act rapidly on the organism would be used during an engagement." Smoke screens, of course, are very largely used in naval warfare, and the author gives some very striking photographs of their production by destroyers and aeroplanes; in fact his view of New York harbour being blotted out by a smoke screen from an aeroplane on May 2nd, 1924, is so startling as to seem almost unreal. In general the measures for individual protection at sea resemble those for land warfare. Closed action stations can easily be rendered gas-proof; in semi-closed stations a plenum fresh air system would expel gas or keep it out; whilst in open stations masks and protective clothing would be required.

In a final chapter Colonel Vedder discusses the possible therapeutic applications of chlorine vapour. During the influenza epidemic the men working at Edgewood Arsenal on chlorine plants practically escaped untouched, and this led to an investigation of the value of chlorine gas. It was found that concentration of 0.021 mgm. of chlorine per litre of air killed bacteria in from 1 to 2 hours. A gassing chamber was constructed with a concentration of 0.015 mgm. per litre and it was found that patients could tolerate this for one hour or more. The results in coryza, chronic rhinitis and bronchitis were distinctly encouraging. In addition to its bactericidal effect, the chlorine gas stimulates the flow of lymph to the mucous surfaces, causes hyperaemia and stimulates phagocytosis. A special chamber has been designed in which it is possible to maintain this concentration for an hour at a time, and chlorine rooms are being designed for hospitals. It is even suggested that, in order to prevent the spread of influenza, infectious catarrh and the like, in cinema theatres and other places ventilated on the plenum system, a certain amount of chlorine might be introduced into the atmosphere prophylactically. Certain diseases however fail to respond to chlorine treatment, such as hay fever, asthma, pneumonia and tuberculosis.

Colonel Vedder's very interesting book should appeal to a wide circle of readers. It is essential for the administrative military medical officer, who may at any time be faced with the necessity of devising a medical organisation against gas. It will also interest chemists, pathologists, and medical men in general.

R. KNOWLES.

THE AIMS OF A MEDICAL MAN.

By C. A. BENTLEY, M.B., D.P.H., D.T.M. & H.,
Director of Public Health, Bengal.

(Being an Address delivered at the opening of the
winter session of the Carmichael Medical
College, Belgachia, Calcutta.)

WHEN your Principal did me the honour to ask me to address you on this occasion I chose for the subject of my remarks the "Aims of a Medical Man." My choice of this subject was largely directed by the fact that I have long been asking myself the question:—What are the present-day objectives of the medical profession?

It seems to me that this is a question that all medical students must ask themselves because, not only in this country but also in the world at large, it now and then appears as if medical men were in danger of forgetting those great ideals which formerly animated the leaders of our noble profession. For many years medical men have rightly prided themselves on the fact that as a class they have almost invariably placed the care of their individual patients and the welfare of the community before their own personal interests. In fact it had been largely true of medical men, in the past:—

"Then none was for a party,
Then all were for the State;
Then the great man helped the poor,
And the poor man loved the great."

But times have changed, and nowadays we hear of doctors combining just like labourers and artisans in trade unions for the purpose of enforcing their demands, and threatening to "strike" if those demands are not acceded to. Recently a circular from the secretary of an important medical organisation came into my hands; this organisation claims to represent a most powerful body of medical opinion whose object is stated to be "*the promotion of the medical and the allied sciences and the maintenance of the honour and interests of the profession.*" And on reading the circular I was amazed to find that it said very little about the promotion of science, and nothing about the honour of the profession. On the contrary it was mainly devoted to a description of the material advantages that medical practitioners might expect to receive if they became members of the Society. Indeed, the greatest emphasis was placed upon what were termed medico-political and social advantages. And on referring to the appended list of the current medico-political activities of the Society to see what its aims actually were, I discovered that every one of the objectives mentioned was related to the remuneration to be received by medical men, especially in cases where they were employed by the State or by local authorities. Now this is evidence of a most regrettable state of things. And I may state at once that it is a grave departure from the traditions of the noblest of "those three noble professions" which to quote the words of Sir Thomas Browne "all civil commonwealths do honour." Fifty years ago this same great medical society of which I speak was taking the foremost part in the work of sanitary reform, and was using all its prestige and influence to impress upon the British Parliament the need of efficient public health legislation. These were medico-political activities worthy of the name; and it was disinterested efforts of this kind that have earned for the medical profession the honourable position that it has so long commanded. In those days it seems to me medical men must have imbibed much of the spirit of Sir Thomas Browne's *Religio Medici*, and must have echoed, perhaps, unconsciously the words of this great physician who wrote and practised in England 250 years ago. "I feel not in me," said he, "those sordid and unchristian desires of my profession; I do not secretly implore and wish for plagues, rejoice at famines, revolve ephemerides and almanacs in expectation of malignant aspects, fatal conjunctions and eclipses. I rejoice not at unwholesome springs nor unseasonable winters; my prayer goes with the husbandman's; I desire everything in its proper season that neither men nor the times be put out of temper."

"Let me be sick myself, if sometimes the malady of my patient be not a disease unto me. I desire rather to cure his infirmities than mine own necessities. When I do him no good, methinks it is scarce honest gain, though I confess 'tis but the worthy salary of our well-intended endeavours. I am not only ashamed but heartily sorry that, besides death, there are diseases incurable; yet not for my own sake, or that they be beyond my art, but for the general cause and sake of humanity, whose common cause I apprehend as mine own."

It is sentiments of the kind just quoted which have long inspired the best aims of the medical profession of every country, and I am proud to say that, in spite of occasional lapses from this high standard of ethics as in the case of the regrettable circular to which I have previously alluded, medical men in every part of the world continue to show, by their noble actions and example, that they regard the welfare of humanity as of more account than personal interest and advancement and as a class prefer honour to gold. If this were not so how can you explain the fact that the death-rate among medical men usually exceeds that of the general population at the corresponding age periods of life? Why was it, I may ask that in the Crimea the French army lost 18 per cent. of its non-combatant surgeons, while the deaths among its combatant officers were only 7 per cent. And why was it also that during the great typhus epidemic in Ireland in 1843-47 the death-rate among medical men was 66 per 1,000, no less than 32 per cent. of those dying falling victims to typhus, whereas among the general population only 9 per cent. of deaths were due to this disease. It is not lust of gold or personal advancement that will explain figures like these which are practical evidence of noble aims and high ideals.

There is a remarkable book, published in 1918, entitled *The Science of Power*. In this book which I should like you all to read, the late Professor Benjamin Kidd calls attention to what he terms "the emotion of the ideal." He states that it is this emotion of the ideal which is the greatest power at work in the world to-day. In his view the Great War itself affords a striking demonstration of the fact that the vast majority of mankind in every country, when actuated by this emotion of the ideal, are willing to sacrifice all hope of personal comfort and material gain and even life itself for the attainment of what they believe to be the common good. And he goes on to develop the thesis that it is this spirit of sacrifice for an ideal that will prove the most potent of all the influences that are tending to shape the social integration of the future. It is true that some critics of this book have characterised it as "a panegyric of masochism and slave mentality." But we may well ask cynics of this sort, what has become of the "cult of the superman" and where are now the disciples of Nietzsche who taught Germany that purely material gains were the only aims worth working for? Surely the results of the Great War should have demonstrated to every one, but the few who are morally blind that materialism is a hopeless doctrine. And to quote the words of the *Bhagavat Gita*:—"These men in spite of grand And flowery speech, which teach of birth

And fruits of action done on earth;
And how by various rituals done,
Wealth, power and worldly joys are won;
Deceived are they by doctrine vain;
And strive for pleasure, wealth and gain.
Their wisdom sure can never stand
On action's true communion ground."

Truly it has been well said—"What shall it profit a man if he gain the whole world and lose his own soul?" And now let us turn from the general to the particular and enquire what should be the special aims of a medical man. If we look up the words medicine, medical, and medicinal in the dictionary, we shall find that they all pertain to that which is applied for the cure or lessening of disease or pain. Now the word medicine itself is derived from various Latin words, i.e., *medicus*, of which relate to healing, or *mederi*, *medeor*, *medicare*, all of which relate to healing, or to restoring. We find also that the Latin word *mederi* is related also to *meditor* or *meditare*, to meditate, and that this in turn is again related to the Greek *medos*, meaning care. Primarily, therefore, a medical man is one who professes to heal or who at least seeks to heal. Now let us ask ourselves what healing is. The dictionary tells us that:—

Heal means to make whole and healthy, to cure, to remove or subdue what is evil, to restore to soundness, to remedy or repair.

Here then we find a ready answer to the question "What are the true aims of a medical man?" Briefly:—

- (1) To make whole.
- (2) To make healthy.
- (3) To cure.
- (4) To remove or subdue what is evil.
- (5) To restore to soundness.
- (6) To remedy.
- (7) To repair.

Carrying our analysis a little further, we may ask, "What is health?" Health is wholeness, and the word *heal* is itself derived from an old Anglo-Saxon word meaning literally, *whole, perfect, or healthy*. And if we push our enquiries still further we shall find that there are a vast number of other important concepts grouped round this great central idea of health and healing. For example the word *hail*, meaning to salute, is derived from the act of wishing a person good health; and the very word *salute* also has a very similar derivation from the Latin *sanus* meaning sound, or *sanitas* meaning health, or *sanare* meaning to heal.

But there is another very significant word closely related to the word "health" and the idea of healing to which I want to draw your attention. This is the term *holy*, which as you will readily perceive brings the conception of the healing art very close to religious duties and aspirations. And if we were to carry our investigations still further we should find also that the ideas embodied in the very terms *sancti*, *sanctum* and *sacred* are in the end bound up with similar notions of wholeness and perfection. When we remember these facts we shall realise that it is by no means strange that the early history of the practice of medicine in every part of the world shows that the art of healing has always been closely associated on the one hand with priesthood, and on the other with the teaching and practice of religion.

Now there is another important point to which I wish to draw your attention. You will observe that the word *healing* and the phrase *to heal* do not imply action taken for personal advantage, on the contrary they suggest something done to benefit others. Everyone knows that the sentence "*Physician heal thyself*" was both meant as a jibe and understood as such. In fact medical men are constantly engaged in healing others, and as incidents in the lives of thousands of medical heroes have frequently proved, very often it is a case of "he saved others, himself he could not save." And here I may observe that the very words *safe*, *save* and *saviour* are also connected with the idea of health or making whole, and so also is the word *redeemer* which is often used in the same sense as *saviour*.

Now we do not call a man who merely saves himself a saviour, but we apply that term only to one who saves others, and in this sense all medical men are saviours. Everyone must know of instances in which medical men have saved the lives of others at the cost of their own. A few years back a medical man in the Darjeeling district, who was well known to me, while lying sick of influenza with a temperature over 101°, many miles away, had a temperature of 106°. There was no one else to go and my friend rose from his sick bed and rode through the inclement weather to the bed-side of the patient. After doing what was necessary for his patient, he found that by an error a temperature of 106° had been written instead of 100°, the doctor returned to his own sick bed, never to leave it except as a corpse. Now while one may regret the error which led to a needless sacrifice, no medical man can help feeling a thrill of pride every time he hears of such a case to think that it was a member of the profession to which he himself belongs who at the call of what he believed to be his duty willingly laid down

his life, for the sake of his patient. Let us contrast this incident with another which came under my personal notice many years ago in a Bengal district. In this latter case a fairly prosperous cultivator lay ill with small-pox. His relations sent for a qualified local practitioner, but the doctor refused to come until a fee of Rs. 32 had been placed in his hands in advance. On receiving the money the doctor went to the house of the patient, but while passing through the court-yard he saw standing there a pony and a pair of bullocks and promptly demanded that these should be given to him in addition to his fee, at the same time threatening to take his departure without seeing the patient unless this was done. I regret to say that he got the animals and afterwards saw the patient, who died a few days later. Now I ask you which of these two medical men whose conduct I have described, deserved the trust and honour of his fellow men? The one lost his life, but left behind him enshrined in the hearts of all who knew him a living memory of goodness and self-sacrifice. The other may have secured material wealth, but his gains could bring him nothing but bitterness of soul and poverty of spirit.

Besides being a healer, a saviour, or saviour of his fellow men, a medical man must possess certain other special qualities of which we find some indication in our brief study of the derivation of the word *medical*. We saw that this word was closely related to the Latin word *meditare*, meaning to meditate; and to the Greek word *medos*, meaning care. Obviously, therefore, a medical man should be both a meditative man and a careful man. As a meditative man he must be a thinker, a student and a learner, always imbued with the divine curiosity which will make him an investigator and a patient seeker after truth. He must likewise be a careful man, because it is his duty to care for or to cure bodies, just as it is the duty of the priest to be the curator or "*curé*" of souls. This brings me back to another important point. You will remember that I have already alluded to the fact that the art of healing was at one time practised by the priesthood.

It follows that in those early days the care or cure of the body was directly associated with the care or cure of the soul. You will also recollect that I told you that the word *holy* which is obviously related to the practice of religion originally meant exactly the same as *whole* or *healthy*, from which it follows that a healer must originally have been one who not only made people healthy, but also made them holy. If this is so it is obvious that a medical man should in the very highest sense be a religious man. Now this is a very important conception, because you have probably often heard it said that nowadays science and religion are antagonistic, and it is sometimes assumed that because a medical man is a scientific man he is, therefore, bound to be more or less sceptical of religion. This is a grievous error. The idea that science has destroyed the foundations of religion is absurd. The teaching of Einstein in regard to relativity and much of the recent work that has been done on psychology afford convincing evidence on this point. Einstein has shown that all knowledge is relative. Even the most exact sciences cannot lead us to a knowledge of the absolute. On the contrary you may be certain that the teachings of science are limited and partial in proportion as they appear most logical, most exact and most conclusive. By this I do not mean in any way to belittle science and scientific work. Science has a most important function to perform and we cannot do without it. But like the special sense organs such as the eye and the ear the usefulness of science depends just as much upon what it ignores and excludes as upon what it reveals. In fact science could not reveal as much as it does if it did not at the same time exclude everything that was not strictly relevant to the subject under immediate observation. Thus it gives us very brilliant illumination over a limited area, so that the important facts with which it deals stand out clear and distinct, but at the same time unless we are careful the

very brilliance of the illumination tends to dull our appreciation and obscure our vision of other facts that are not included within our purview at the moment. If you have been working in a brilliantly-lighted room and then suddenly go out into the badly-lighted street, you know what happens. For a time you cannot see, everything appears dark and you may easily stumble against objects that are clearly visible to those whose eyes have not been dazzled with an excess of light. So it is with some scientific men, who become so dazzled with the excess of light in their own narrow sphere of thought that they become blind to the great truths of religion that are clearly recognized by those who have retained a wider outlook on the problems of life in general.

Science deals with the particular rather than the general, and more especially with what we term the material; and as you know, its methods are largely those of analysis. Now while it is very important that men should study the particular,—in other words that some of us should specialize in order that the sum total of knowledge may be increased; and while for this purpose analytical methods may be of great value, we must never forget that specialization and analysis have their own limitations. A simple illustration will demonstrate this fact. Just let us imagine for a moment that an intelligent inhabitant of the planet Mars, possessed of faculties and training very similar to our own, were to pay a visit to Calcutta, descending on the *maiden* near the Victoria Memorial. Let us suppose that that huge building were to attract the visitor's notice and prompt investigation, and that he were to apply scientific methods of analysis in order to satisfy his curiosity. Let us imagine him saying to himself "here is a huge mass of material which possesses a peculiar shape suggestive of some definite function and purpose; let me discover what it is composed of so that I may understand it." Let us imagine that he was able carefully to take the building to pieces, beginning with the dome and gradually descending to the foundation, and that every stone was counted and was duly classified according to its shape, size, or some other standard.

When the work of destruction was complete all that would be left of the Victoria Memorial would be a number of neatly arranged piles of material and an accurate inventory of the contents of each pile. And even if our visitor had taken the trouble while demolishing the building, to prepare careful plans of it so that he could afterwards reconstruct it, he would still remain entirely ignorant regarding its origin, its purpose and the various ideas and emotions which it embodies and symbolises. Yet it is apparent that a knowledge of these very matters is absolutely essential for a true comprehension of the Memorial and all it stands for. Now if you have interpreted this little parable aright it will help you to an understanding of the respective functions of science and religion. The main task of religion is to do what science cannot do, to comprehend life, for religion is concerned with life as a whole, whereas science merely deals with various aspects of life. Once you have grasped this fact you will realize that science and religion can never be really antagonistic, and that science can never replace religion, but that both are necessary to the welfare of mankind.

Medical men are concerned in a very special manner with the welfare of mankind, for the aim of the medical profession for countless ages has been to discover in what that welfare consists and how it may best be secured. Nearly 2,500 years ago Hippocrates established a noble order of priesthood in the temple of *Æsculapius*. In those days the physicians were priests, the places in which they worked were holy, and the arts of healing that they practised formed a sacred ritual. In those days also, before anyone was admitted to the great order of doctor-priest or priestly doctor he was obliged to swear a solemn oath always to do his duty to his patients, to reveal none of their secrets, and to consider himself not all where their interests were

concerned. And although times have changed, the young medical graduate is usually required, even at the present time, to take the same great Hippocratic oath when he receives his degree. It is not without good reasons, therefore, that I have impressed upon you the fact that a medical man should always be a religious man; for the profession he has chosen is a sacred calling and the oath that he has taken is a religious vow.

A recent medical writer in the *Observer* has wittily remarked:—"Druggists should dispense drugs; doctors should dispense doctrine." And as you will readily perceive, I have endeavoured in this address to follow out the above suggestion by avoiding all reference to drugs and confining my remarks entirely to doctrine.

Finally, as a fitting conclusion to the doctrines I have been dispensing, I wish to direct your attention to some of the wonderful teachings which you will find in your own great *Bhagavat Gita*. What better guide to conduct can anyone find, be he a medical man or a layman, for example than the following:—

"Those men who do to others great and small
What good they can, and rule their passions all.
Who see all equal and do none disdain,
They too—the spirit seekers—Me attain.

"Whate'er you do, enjoy or give, endure
Whate'er perform of rites and worship pure.
O Kunti's son! all those in Me resign,
And never think that fruits or acts are thine.

"By working thus, from bonds of action free—
Fruits good or evil both—wilt gain thou Me,
In Me resigned entire, the holy soul
Doth Me attain all free from world's control.

"Of fruits regardless wont to be,
From chains of birth forever free;
The learned joined to wisdom gain
A state diseaseless, free from pain.

"The patience by which one can well control
The working of the senses, life and mind,
Which fixed on these does want no other goal,
That patience, friend, is of the saintly kind.

"The wise with knowledge such do Me adore
And from their inmost heart devotion pour;
They live in Me, they have their minds in Me
And 'mongst themselves, expound My nature free.
And still of Me do talk and thus do gain
Contentment, sure purest joy attain.

"As boats by gales and storms are tossed
Now here, now there, and often lost;
So human wisdom by a mind
Which follows senses wild and blind,
Is driven and dashed and made a wreck,
So keep thy senses well in check.

"Yet not as sin enjoyment shun,
Enjoy the world; but see 'tis done
With senses under self-control
And free from love and hate; the soul
Enjoying objects thus doth gain,
Contentment void of earthly pain."

HINTS TO MEDICAL MOTORISTS.

By J. W. D. M.

THE motor car has now become an essential article of equipment of most medical men. To the doctor time is money,—often it is something more,—a human life.

To the motorist who leaves his car entirely in the hands of a paid driver, motoring is expensive; but to the man who takes an interest in looking after it and who drives it himself the car becomes an inexpensive means of travel and also an interesting hobby.

From the nature of his training the medical man should have little difficulty in learning about the

mechanism of his car, and when trouble arises he ought to be able to deal with the emergency with greater efficiency and resource than can be expected from an unintelligent driver.

We can strongly recommend motoring as a healthful and money-saving hobby to those who find a car a necessity in their daily work.

These notes are not intended to take the place of a book of instructions. Every motorist worthy of the name will learn the theory and practice of the internal combustion engine from one of the excellent books which are published; he will also carefully study the book of instructions which is supplied with his own make of car.

The first essential of the good motorist is to learn to leave his car alone as much as possible. He will see that it is properly oiled and cleaned, and he will periodically go over the car to see that the nuts are tight, but he will never undo a single nut unless there is a good reason for doing so. The car has been put together by experts, and when any important part has been dismantled it will seldom be so well re-adjusted as it was when it left the works. Meddlesome interference will shorten the life of the car nearly as much as neglect.

It is not necessary to do the work of oiling and cleaning as a routine, but once a month or preferably once a week the owner should go over the car and see that the driver has not forgotten to oil some essential part simply because it is not in an easily accessible position.

The first problem in connection with a car is its purchase, and it is in this matter that the beginner often has to buy his experience dearly. He should decide whether to buy a new or second-hand car, and as a rule the beginner will be well advised to go in for a new car unless he has complete information as to the condition of the second-hand car of his choice.

The commonest mistake is to be tempted by a large, cheap, second-hand car. The imposing-looking mount often looks dirt-cheap at the price, but when the cost of repairs and running and the difficulty in getting rid of the car are considered the owner will often have cause to regret that he has bought a white elephant. If, on the other hand, he has an opportunity of buying a car which has been in use in his own station, if he knows its history from the beginning, and if he has the assurance of a real expert that the car is in sound condition he need not hesitate to buy a second-hand vehicle. Let him, however, estimate the cost of a new set of tyres, a coat of paint, perhaps a new hood and a general overhaul should these be necessary.

In buying a new car there is a bewildering array of models from which to choose, and there is no "best car" for all possible purposes. For certain kinds of work the humble Ford will be most suitable; for others one of the small English or French cars will be more satisfactory.

The points to consider are:—

1. The smallest car which will serve the purpose should be selected, as the cost of tyres and petrol will be less, especially if long distances have to be covered. In every case a small, good car is a better bargain than a larger second-rate mount.

2. A car which is popular in the locality should be selected unless the owner is an expert and can rise superior to considerations of repair facilities and second-hand value. Of two cars which are equally good, the one which is best known in the locality is always most satisfactory, especially for the beginner.

3. If bad roads have to be traversed see that the clearance of the car is sufficient; for really bad roads the Ford in some cases is the only possible vehicle. If the roads are good the small English or French cars are usually preferred.

4. The type of body will depend on circumstances; as a rule a light four seater is the most serviceable, especially if touring has to be done. For station work a light two seater with a dicky seat will be chosen if

the car is only used by the doctor himself and not as a family conveyance.

Heavy closed cars are more expensive to buy and to run, and in India the body work will give far more trouble than that of the open car.

When first you decide to buy a car make a fair estimate of the real cost. Make allowance for interest on the capital cost, depreciation, repairs, tyres, petrol and insurance. You will perhaps be a little surprised at the real cost of keeping a car, but if you have begun by counting the cost you will probably be agreeably surprised to find that your estimate has been in excess of the reality; whereas if you count only tyres and petrol you will be seriously disillusioned when you make up your bills for the year.

Depreciation is an item which varies enormously. If you buy an expensive new car and have to sell it at the end of a year or two, thirty per cent. may not be too much to reckon; but if you drive your car carefully it may still be worth a good deal at the end of ten years of steady work, so that the depreciation will work out at considerably less than ten per cent. A fair average for a good car, carefully used, is twenty-five per cent. for the first year and ten per cent. for each successive year.

In the case of a really good, cheap second-hand car the depreciation may work out as low as five per cent.; but if you have bought one of the white elephants already referred to, the depreciation may easily be fifty per cent. or more in the first week.

With present prices motoring is now much cheaper than formerly. It is quite common to find small cars which will do thirty or thirty-five miles to the gallon over long runs, and tyres which are properly looked after will do close on ten thousand miles, so that running costs for the owner-driven small car will work out at surprisingly low rates.

In the case of a good new car, repairs should cost next to nothing for the first year and very little even in later years.

Hints on the Management of the Car.—Go slow at first, and if you have any trouble find out what is the matter. Do not carry on with a lame car in the hope that it will right itself; you might as well advise a patient to carry on with a sprained or fractured leg as to drive a damaged car.

Starting up may give a lot of trouble at first. Don't use your self starter when the car is cold, you may ruin your battery in vain attempts to start a car which is wrongly adjusted, and you may find that you have damaged or destroyed your battery, while the trouble is due to the petrol not being turned on or the ignition being switched off.

If the car refuses to start at once find out what is the matter. See that the petrol is reaching the carburettor; that the switch is on; and that your compression is right. If these points have been attended to and all the levers are in their proper places, and yet the car will not start, see that the make and break of the magneto has not stuck up; that the valves are closing properly; and that the plugs are clean and are sparking properly. If the car still gives trouble get an expert to help you. Some cars are naturally difficult to start in the cold, especially if the jet of the carburettor is small and is set for economical running. Under these circumstances flooding the carburettor or fitting compression taps and pouring in a few drops of equal parts of petrol and ether into the cylinders will set matters right. But remember that in some cars flooding the carburettor causes the mixture to be too rich, and the remedy is to give more air and work the engine by hand until the excess of petrol has been disposed of. When the engine is hot don't flood the carburettor before starting; you will make the mixture too rich and the car will stutter and refuse to start.

Driving.—The beginner should spend a good deal of time in learning to manage his gears; to start without straining the transmission; to reverse and to apply the brakes gently but firmly. Straightforward driving on

the open road is so easy and attractive to the beginner that he often goes for long distances before he has really learned to drive properly. Before you drive a yard be quite sure that you know how to stop the car instantly and how to manage the gears and clutch.

At first you should select an open and secluded place and be quite sure that the car is fully under your control before you risk your car and the lives of pedestrians.

One of the chief difficulties of the beginner lies in gear changing, but an hour's practice in changing up and down will teach you far more than several days of driving on the open road.

You are not a competent driver until you can change up and down without noise and jar; and the little trick called double declutching should be mastered straight away. You will meet people who have driven a car for years who still dread changing down. The result is that they stick to top gear when the car is calling loudly for the second gear; the whole mechanism is seriously strained as a result.

It is important to learn by experience the engine speed which approximately corresponds to the speed of the car not only in the top gear but also in the low gears, and to let in the clutch only when the engine speed and the road speed correspond with each other. For instance, if the engine is racing with the clutch disengaged, you will seriously strain the car if you go into top speed while the car is at rest or moving slowly; and on the other hand, if you attempt to go into low gear with the car travelling rapidly, the effect will be that the gears will be damaged or destroyed.

To start from a standstill let the engine run quietly at a moderate speed, take out the clutch, put in the lowest gear and then engage the clutch very gently but deliberately so that the car moves forward without a jerk. As soon as the car is moving take out the clutch, promptly get into second gear and again engage the clutch. Gradually accelerate until the car is moving at a pace of at least ten to twelve miles an hour; take out the clutch, let the engine slow down, get into top gear and then let in the clutch. In each case accelerate the engine gently just as the clutch is being let in.

In changing down from top speed to second the manoeuvre of double declutching is most useful. This sounds a little complicated when described, but in practice it soon becomes very easy, and when you have mastered the art you will no longer have the temptation to remain in top gear when the engine is labouring and demanding to be put into second speed. The steps are:—

1. Take out the clutch.
2. Put the gear into neutral.
3. Let in the clutch again for a moment while in neutral.
4. Take out the clutch and instantly go into second gear.
5. Let in the clutch again.

Try to keep the engine at the speed at which it ought to travel when the car is moving at the actual pace in the second gear.

With a little practice you will get into second speed every time without the slightest noise or jar, especially when you have found the right degree of engine acceleration which suits second gear at the pace at which the car is travelling. Most drivers cling desperately to top gear because they are afraid to change down to second and because they are proud of doing everything on top speed. When you remember that your engine and transmission work most efficiently and with the least strain at a fairly high engine speed, you will realise that it is a mistake to climb hills at a slow speed on top gear or to accelerate from a speed of four or five miles an hour on top gear. The proper method is to get into second gear as soon as the car slows down to ten or twelve miles an hour or so, and to get into top only when you are travelling easily at a higher speed than this.

The exact time for changing down varies in different cars. With a powerful six-cylinder you can easily accelerate on top from six miles an hour or so, but with the small high speed engines of the light cars it is a great mistake to cling to top gear at low speed.

Make sure that your brakes are acting properly and that they grip both wheels equally. If in doubt as to this jack up both wheels and spin them while someone applies the brakes gradually. If both wheels stop together, your brakes are acting properly; but if one grips while the other does not act, an adjustment is necessary. In the case of four wheel brakes see that the front wheel brakes act equally and that they act a little before the back wheel brakes. Having adjusted the brakes and tested their efficiency under running conditions, drive without using them, except in an emergency. The good driver will allow his car to come to rest without using the brakes, and he will avoid getting himself into tight places in which sudden application of the brakes is needed. A single fierce application of the brakes will damage your tyres as much as several hundred miles of straightforward driving and will also strain the mechanism.

At corners of streets you must always assume that there will be an obstacle just round the corner; always drive in such a way that you can pull up easily within the distance that you can see ahead.

In streets assume that a child is likely to rush across the street from every doorway, and so keep your car thoroughly under control.

Be sure never to pass a vehicle without seeing a clear road ahead.

On a slippery road there is no means of avoiding skids. A skid is rarely serious if you are going slowly, whereas at high speeds disaster is likely.

Economy in petrol depends on driving at a moderate speed suited to your car, on the perfection of the oiling and adjustment of the engine, on the proper adjustment of the carburettor,—especially of the jet,—on closing the petrol tap when you stop, on the proper adjustment of your spark advance and on the perfection of your compression. If you pour a little oil or water round your sparking plugs and cylinder caps you will often find that air is escaping when the engine is running. New washers or tightening up the plugs and caps will completely stop this and you may get four or five more miles to the gallon of petrol in consequence of a few minutes' work.

If your engine knocks there may be need for decarbonisation or possibly your ignition is too far advanced. A knock is always a signal for an examination to find out and rectify the cause.

If the beat of the engine becomes irregular, look first to your plugs; see that the wires are securely attached at both ends, then test the plugs while the engine runs slowly by using one of the simple plug testers that are on the market. When you have found which plug is not functioning, remove it and clean it thoroughly with petrol and look to the separation of the points. Keep a few new washers for the plugs and always use one after taking out a plug.

If the water boils in the radiator under circumstances in which there is no special strain on the cooling system, look to your fan and radiator. If these are in good order there is likely to be too great a retard in the spark or the mixture may be too weak.

Do not tolerate a fierce or slipping clutch,—either defect will cost you dear. Immediate attention is essential. You may merely have to adjust the clutch pedal or the lubrication may be defective.

In the older type of car you may have to allow your clutch to slip a little on certain occasions; in the newer high speed engine you should not slip the clutch at all, you must change down when the engine shows signs of labouring.

Tyres must be kept at the proper pressure. A special tyre gauge must be used; the gauges which are supplied with pumps cannot be relied on.

A foot pump with a self-fixing connection for the tyre valve is a great comfort; it is instantly attached and does not allow of escape of air.

If your front tyres show signs of rapid wear, have your wheels tested to see that they are exactly parallel. After a collision or even from wear and tear the wheels may get out of alignment and it is not uncommon for tyres to wear out within a few hundred miles on account of this.

Balloon tyres are coming rapidly into use on small cars. They slow down the car very slightly, but owing to the way in which they yield to inequalities on bad roads they allow of a much higher average speed than ordinary tyres. They also save the machinery from shocks and give you great comfort on rough roads. They may be fitted to ordinary rims if the clearance between the front wheels and the chassis is sufficient, but it is more satisfactory to have them fitted on the car from the beginning. Most makers now supply them as standards or on special order. In the case of large cars you need not fit them unless the makers recommend their use.

Keep an eye on your battery. It is more likely to give trouble in India than in cold climates, and if you live in places away from workshops you will find it desirable to fit oil side lamps or to keep a pair in reserve in case of battery failure. On the whole it is better to stick to magneto ignition rather than to trust to battery ignition alone. In the latter case if the battery fails your car will be thrown out of commission.

Don't use your self starter too much. It is better to use the starting handle in the morning or in case you have to make very frequent halts after short runs.

Don't spend a lot of money on accessories. Most cars are already supplied with all that are needed. A speedometer is useful, so is an electric horn, shock absorbers, a fire extinguisher, a radiator thermometer, and a petrol gauge, by which you can see from the driving seat how much petrol is in the tank. The gauge can easily be fitted to dashboard tanks, but is hardly practicable for pressure-fed tanks such as are fitted on many large cars.

If you are held up by a broken spring, get two flat pieces of iron,—even tyre levers will do,—place one above the spring and the other below, bind them tightly with a strong piece of cord, wet the cord and it will grip still more tightly, then go slowly home and arrange for a new spring leaf or for a proper workshop repair.

You will save many rupees a month if you drive yourself, and if you spend an hour once a week in attending to the toilet of the car.

The good driver is not only considerate of his own car, but also of the other users of the road. Cattle and drivers of bullock carts may be relied on to do the wrong thing, not out of perversity but from ignorance, and it is your duty to make every allowance for them. Merely getting angry with them will not compensate you for a damaged or disabled car, so it is in your own interests to observe forbearance and foresight.

You will soon find that it is false economy to go on using a damaged tyre. You may get an extra hundred miles out of a groggy tyre, but as a rule you will destroy a good inner tube and probably have a lot of trouble on the road, and these will far more than compensate for the scrapping of the tyre a little earlier than is absolutely necessary.

Even if you don't make a practice of changing a wheel or tyre you ought to master the art of doing so. You will save money and trouble by seeing that the rims are thoroughly clean and dry before a new tyre is put on; also by seeing that the nuts of the wheels as well as the false axle on which the detachable wheel fits are greased or oiled. If these parts get rusty you may have a terrific struggle to change a wheel when you have a puncture. Also test the tightness of the nuts which hold on your wheel; these are likely to become loose after the wheel has been changed, so look to them after a few miles of running.

Most owners are careful to see that the outside of the body work is in good order. It is equally important to keep the concealed woodwork well painted. The same applies to the under surfaces of your mud-guards. Rust and rot cause a heavy addition to your bill of costs if you do not attend to these points.

Rattles and squeaks should be located as soon as possible, and it is a good thing to go over all the nuts on the car now and then, especially those which hold the springs on their seatings.

Have a good chamois-lined petrol funnel and see the petrol poured in for yourself. Attention to this point will save you the unpleasant experience of having to clean out an obstructed carburettor when you are in a hurry to visit a patient.

It is pretty certain that the careful owner who drives his own car can cut down his motoring expenses by twenty-five or thirty per cent. as compared with the man who leaves everything in the hands of a paid driver. The bills for wages, petrol, oil and tyres will be much less, and his car will last at least twice as long.

The writer of these notes has been an owner-driver for the past seventeen years. He has not always practised what he preaches, but by spending an hour once a week on his car he has kept his motoring costs down to a figure which would have been entirely unattainable to the owner who trusts to the tender mercies of a paid driver. He has also obtained a great deal of pleasure from his cars; one of which is in perfect running order after thirteen years of hard wear.

Wounds and other Injuries in their Medico-Legal Aspect.

A LECTURE delivered before the Medical Society of London by Sir Bernard E. Spilsbury, M.B.—*Lancet*, February 28th, 1925.

The following extracts from the first lecture will be of interest.

A contusion, or as it is commonly called, a bruise, is a crushing injury produced either by excessive pressure upon the surface of the body, or by violent contact with an object which is relatively incompressible, and which is of such a form as to produce no gross injury to the surface.

The resulting hæmorrhage is more rapid and profuse, and instead of infiltrating it pushes aside the crushed tissue to form a cavity filled with blood—a hæmatoma. A very similar effect is produced by a foreign body such as a bullet tearing its way through the tissues; if its progress is arrested by the skin a bruise speedily forms in the subcutaneous tissues around it. It is the causative hæmorrhage into the tissues, due to excessive pressure within the blood vessels, or to disease of the blood-vessels and tissues. If the violence is maintained until death, and for a short time afterwards, there may be no escape of blood from the torn blood vessels, the only effects of the crushing force being some pitting of the skin, and perhaps slight softening of the damaged area; usually, however, a little blood escapes at the margin of the crushed area and the hæmorrhage becomes more evident if the compressing object alters its position. This explains the slight amount of bruising which may result from the pressure of the fingers of an assailant upon the neck of the victim in a fatal case of throttling, although the violence may have been so great as to have led to the production of hæmorrhage in the loose cellular tissue between the larynx and the spine.

A bruise inflicted shortly before death, which is not visible on the surface of the body, may become apparent a few hours or several days after death. This is

due to a more rapid hæmolysis in the stagnant blood as a part of post-mortem changes. The pigment diffuses locally, producing a stain in the surface, dark red at first, but changing sometimes to a brief red colour from absorption of oxygen through the skin; or an area of dark green putrefactive discoloration appears over a deep bruise before the skin around it is changed. Two minutes after death no appreciable bruising occurs and the amount of blood effused, when death follows immediately upon the infliction of the injury, will be slight in comparison with the amount when the injured person survives.

Sir Bernard has seen several cases in which death resulted from the shock of multiple contusions.

In one, a woman about 45 years of age, who had been brutally assaulted and who was found dead in her apartment, six bruises were found on examination of the body: three of these situated on the face and head were of large size and were caused by severe crushing. There were no open wounds upon the body, little blood had been lost, and there was no disease to account for the death.

Crushing Injuries of the Chest and Abdomen.—Chiefly by motor vehicles but also by falls from a height, crushes by falling debris, by railway trains, and in lift accidents, and by severe blows on the chest and abdomen by cart-poles, kicks by horses, etc.

An examination of the results shows that in one-half of the cases no external injury—not even a bruise or the mark of a wheel—was present at death on the surface of the chest or abdomen; in a large proportion death was due solely to injuries of the organs in these regions, and ribs were fractured in 75 per cent. of the cases. Recorded cases of injury of the chest and abdomen include many in which no external injuries were seen, and I was surprised to find that they occurred in so many of the cases in this series.

Effects Produced by Passage of Projectiles through the Tissues.—If discharged within a short distance of the body there may be surface indications from which the distance of the weapon can be accurately determined, and the path of the projectile through the body enables the exact position of the weapon in relation to the victim to be determined and may give valuable information as to the medico-legal significance of the wound. When the projectile penetrates another object after traversing the body it may be possible to reconstruct exactly the circumstances in which the weapon was discharged, whilst the firm grasp of the weapon in the hand of the victim after death gives a clear indication of a self-inflicted injury.

When a weapon is discharged near the body the external markings are seen principally upon the skin and clothing around the entrance wound. They vary with the type of cartridge and the nature and amount of the charge and are less distinct when smokeless powder is used. The changes produced by black powder are due to flame when the discharge is very close, to smoke for a rather longer distance, and to unconsumed powder at a still greater range. Flame may singe or set fire to clothing, singeing the hair and slightly burning the skin, with the formation of a glazed, brown, parchment-like area after death. Smoke, when the discharge is fairly close, produces a uniform black deposit, and grains of unconsumed powder expelled from the weapon behind the projectile are carried for a distance possibly of several feet, spreading like small shot, and with such force that they are embedded in the skin and clothing, and produce characteristic tattooing.

The pattern produced round an entrance wound in a given case may be reproduced by experiment, using the same weapon and cartridges of the same manufacture; the distance at which the weapon has been discharged may thus be estimated with a fair degree of accuracy.

In cases of self-inflicted injury, blackening and splashes of blood may be found upon the hand used

to steady the weapon at the muzzle end. The external indications of a near discharge may be absent when the muzzle of the weapon is pressed firmly against the skin, the gases of the discharge, the flame, smoke, and powder grains all following the track of the bullet into the body.

Apart from splitting of the skin produced by the gases of the discharge the wound of entrance is generally small, circular when the weapon is discharged at right angles, and oval in shape when the bullet has entered obliquely; the margin of the wound may be inverted, though this is by no means constant.

The wound of exit is often larger and more irregular, especially when the bullet has passed through bone; this is due to deformation of the bullet or to laceration of the skin by fragments of bone expelled by the projectile. Multiple exit wounds may be so produced—and this is more frequently seen when the projectile is large and travels at high velocity, splintering the bone at some distance from the skin. The skin at the margin of the exit wound is often everted.

The following is a remarkable example of self-inflicted injury but the coroner recorded a verdict of accidental death. A young man was found lying on his back on the floor of his bed room, dead, the sound of the discharge of a firearm having been heard a few minutes previously. He lay opposite a looking-glass, his left hand was in his pocket, and the revolver containing one empty cartridge case was found in a closed drawer. He had shot himself through the roof of the mouth, the bullet passing through the hard palate in the middle line and vertically upwards, smashing the nasal septum and the cribriform plate, passing through the cranial cavity between the frontal lobes; the bullet was embedded in the fractured vault at the end of the track, the only injury of the brain being a linear bruise on the mesial aspect of each frontal lobe along the course taken by the bullet. The mucous membrane of the palate was blackened by smoke behind the wound. The front of the chin had been injured, probably by the kick of the revolver, and the lips were bruised and slightly lacerated from the sudden escape of gases at the moment of discharge. Asphyxia was the cause of death, blood having run from the nose into the air passages as he lay unconscious.

This was more probably a suicidal act, though it is just possible that he was imitating a suicide, not suspecting that the revolver was loaded. From the slight amount of injury of the brain by the bullet it is possible that he retained consciousness long enough to enable him to place the revolver in the drawer, at some distance from the spot where he was found, and to close the drawer afterwards.

The following is an interesting example of the reconstruction of a murder of a soldier in camp at Aldershot, who was found dead in a hut at night, shortly after the sound of a shot had been heard. The other occupant of the hut, a soldier, was afterwards charged with murder. The death was at first thought to be a suicide, the coroner was informed; an inquest was held without a post-mortem examination and a verdict of suicide was recorded, the body then being buried. Several suspicious circumstances, however, led to the arrest of the other occupant of the hut, and at the time of my investigation he was awaiting his trial at the assizes.

When he was discovered the dead man was lying on his back, covered with bed-clothes up to the chest, and clothed in underwear and socks; his face, turned to the right, was at the edge of the bed. There was a bullet wound on the left cheek immediately below the malar bone which was not fractured, and the characters of the wound and the changes around it were carefully noted by the medical officer. On turning the head the exit wound was found immediately behind the right mastoid process. The weapon, a service rifle, was on the floor close to the bed and between the outstretched arms of the dead man, but was not grasp-

ed, nor were the hands blackened. The cartridge was a Mark 303. After leaving the head the bullet traversed the bedding and a pillow consisting of a bag containing uniform, and an examination of these showed that no metal or other hard object had been struck; the bullet had then passed through the wall of the hut, constructed of two layers of three-ply wood with a space between. In this part of its course the trajectory formed an angle of 35° with the horizontal; it had undergone no deflection in its passage through the wall, and a furrow produced by its striking the path outside was in the same line.

On plotting out upon a skull the line joining the entrance and exit wounds it was found to cross the central nervous system at the junction of brain and spinal cord; the passage of the bullet must have resulted in instant paralysis, and probably instant death. To bring the track of the bullet through the head into line with the track in the wall the head must have been resting on the pillow in a half lateral position when the weapon was fired, and must have rolled completely to the right immediately afterwards. The weapon must have been pointed in a downward direction at an angle of 35° .

To ascertain its distance from the head experiments were made with the weapon, using cartridges of the same pattern, and the blackening seen around the wound in the cheek was found to correspond with a muzzle distance of more than 2 in., and probably about 5 in. The weapon was $3\frac{1}{2}$ ft. long from muzzle to trigger. The dead man was 5 ft. $7\frac{1}{2}$ in. in height; and it was impossible for a man of that height to have touched the trigger with his finger, with the muzzle 2 in. from his cheek, when lying in bed. The weapon could not have been discharged by his foot, as paralysis would have prevented him from replacing his foot beneath the bed-clothes after the weapon was discharged. The wound, therefore, could not have been self-inflicted, and the prisoner was the only other person who was in the hut at the time. He was found guilty.

Homicide by Firearms.

In cases of homicide by firearms multiple injuries are more frequent than in suicides. If an injury in a vital area is associated with one in the hand or arm it is a strong presumption of homicide. The two injuries may have been caused by one bullet, the arm having been raised to cover the body, and in such a case the arm can be placed in a position so that the two wounds come into the same line.

In homicidal cases the distinction of wounds of entry and of exit is often a matter of considerable difficulty, especially when the weapon is a service revolver or a modern rifle. Discharged at a range of more than five or six feet from the body, there will probably be no mark on the clothing or skin around the wound to indicate the wound of entry, and in size and shape the two wounds may be very similar, especially with the more pointed type of bullet, though the exit wound tends to be more slit-like, and the entrance wound circular.

How Interference in Labour may be Lessened by Examination during Pregnancy.

By JOHN S. FAIRBAIRN, B.M. (Oxon.), F.R.C.P., F.R.C.S.,

British Med. Jl., February, 1925.

ANTE-NATAL supervision is as yet in its infancy, and much still remains to be done to improve its methods of investigation.

So far as possible, investigation of suspected abnormalities should be made as little obvious as can be. The chief aims of the supervision may be stated as:

1. Maintaining health of body and mind in the pregnant woman.

2. Preserving the pregnancy to full time.
3. Foreseeing and avoiding preventable difficulties in labour.

4. Preparing the mother for the nursing and care of her child and generally educating her in regard to her own health and that of her family.

Dr. Fairbairn first discusses albuminuria. The testing of the urine is the first sieve to strain out cases for further investigation, the next point is to determine the meaning of the albuminuria if it is not due to contamination after the urine has left the bladder; then a further chemical and bacteriological examination may be necessary to exclude those cases due to pyelitis or cystitis.

The next point to determine is how far the renal function is affected, for albuminuria by itself is not proof positive of its disturbance. Diminished secretion, the presence of casts, œdema, and raised blood pressure would indicate renal damage, and to determine its degree the urea concentration test should be carried out. As soon as any impairment of renal function is discovered the essential matter is to keep the patient strictly to bed, and observe what rest with a restricted protein intake will do. In most cases the effect of the diminished metabolism is rapid. If, after a couple of weeks, no improvement results, and still more if the continuance of headache and sickness, increased œdema, and persistent high blood pressure show that the condition is both serious and resistant to treatment, the pregnancy must be terminated, for fear of progressive and permanent renal damage, or, more rarely, eclamptic convulsions.

The next point is to discover the position and presentation of the fœtus, the pelvic capacity, and, so far as possible, to detect any factors likely to complicate the labour. This part of the examination is not begun till the last two months of pregnancy—that is, about the thirty-fourth week—as before then it is rarely possible to discover with accuracy the presentation, and, even if it were, a completely different state of affairs may be present a few weeks later.

The general physical development of the woman should be noted, both in the erect position and when lying down. A height under 5 feet, narrowness across the hips, spinal curvature or other deformity, lameness due to disease of the hip-joint or to infantile palsy, should always suggest the need for special care. Bone or joint disease or other condition that has necessitated a long period of lying on the back during childhood may have checked the full development of the pelvic girdle. The appearance of the abdomen should be carefully observed, both when standing up and recumbent, and the size, shape, and position of the uterus noted.

In a first pregnancy, unusual forward projection of the uterus, especially if persistent even in the dorsal position, indicates deficient space in the abdominal or pelvic cavity.

The diagnosis of presentation and position is carried out by the ordinary obstetrical examination, and should be confirmed again later. Rectification of a breech presentation is most easily effected about three weeks before term, and though rectification of the foetal lie and the uterine obliquity by padding and a binder may be tried in shoulder presentations, the more favourable time, owing to the tendency to recurrence, is as a rule at the commencement of labour. In any case in which external version has been done further examination is necessary to see that there has not been a reversion to the original presentation. Face and brow presentations are rarely recognised at the ante-natal examination, and if recognized, are not readily converted to, or maintained as, a vertex. For the most part they arise at the onset of labour, and, as in oblique lies, reliance must chiefly be placed on discovering the high position of the head and the conditions liable to give rise to them, and trust to rectification at the onset of labour. Occipito-posterior

positions are likewise best treated either just before or immediately at the onset of labour by a pad and binder, after the method of Buist.

Pelvic capacity is tested by two different methods—one pelvimetry, and the other the estimation of the fit of the head into the brim.

The abdominal examination is especially important as the simplest method of picking out those cases requiring further investigation. The head high up and floating above the brim is easily accessible to palpation. If it has descended into the pelvic cavity the fingers must be sunk into the pelvis in order to recognize the hard and immovable mass, filling up the sacral hollow. A high position of the head in a primigravida during the later weeks of pregnancy must always be taken as a warning of possible trouble. In multiparae, especially those with a lax abdominal wall, there is neither the same tension within the abdomen to drive the head downwards nor does the uterine axis lie directly in that of the inlet to facilitate descent, and hence a high position of the head has not the same significance.

A rough test can be made of the relation between the size of the head and pelvis by pressing the head downwards from the abdomen. If the two poles of the head, the forehead and hind-head, can be felt very distinctly a transverse position of the head with some degree of extension is probable, indicating some flattening of the brim.

By pressing the head into the brim with the patient in the dorsal position an impression can thus be obtained of the amount of room and of the ease with which the head will enter, and those cases in which difficulty is suspected should then be reserved for further examination by the bimanual method. The treatment of the minor degrees of misfit between the head and the pelvis is by the induction of labour before the child is large enough to cause difficulty, and yet not too small to give trouble in rearing.

If the patient is examined at the thirty-fourth week, and it is then discovered that disparity between the head and the pelvis is such that even at this early stage natural delivery is unlikely owing to a serious degree of pelvic deformity, Caesarean section at term would be selected. These cases are, however, very rare, and in the lesser degrees of deformity the woman would be seen every fortnight. The fit of the head would be judged by rough estimation until difficulty in pressing down the head was detected, when the bimanual examination under anaesthesia would be made in order to decide the most suitable time to induce.

A natural labour carefully observed and conducted will teach us much more than we can learn from the most thorough examination, and in a young woman with twenty years of reproductive life in front of her it is much better for her future to make a trial trip of her first pregnancy and know by experience what the natural powers can do. Usually they will do better than we expect. On the other hand, in a woman who has had previous labours in which induction has failed to give a living child, or in a woman in her first pregnancy towards the end of her reproductive life, Caesarean section would clearly be the preferable method of delivery, as securing her a living child in what might be her only pregnancy.

We know so little as to the causation of ante-partum hemorrhage that our endeavour must be to take the first occurrence of bleeding as a warning of possible further trouble to come.

If placenta praevia can be definitely diagnosed, it is unsafe to temporize. Eclamptic convulsions rarely occur without albuminuria or other warning signs, and thus their unexpected onset is greatly limited by proper ante-natal supervision; they may, however, occur occasionally in patients under observation and treatment for albuminuria, when they are not usually serious, or may develop suddenly with little warning.

Indian Diets in Relationship to Health and Disease.

At a meeting on April 15th, 1925, of the Medical Section of the Asiatic Society of Bengal, Major H. W. Acton, I.M.S., read a joint paper (by himself and Major R. N. Chopra, I.M.S., on "Indian Diets in Relationship to Health and Disease."

The author, in this paper, presented an analysis of Indian dietaries under different conditions of health and disease. Indian ideas on diets were entirely different from European ones; thus the Indian considered that milk was laxative and not constipating, and that it should not be prescribed in bronchitis. The view that meat was unsuitable for the Indian was borne out by the fact that in most Indians the gastric juice was deficient in acid and pepsin. Again the order of a meal as partaken of by an Indian was entirely different from the order followed by a European.

Susruta divides the different articles of food into three classes:—

- (1) Those absolutely beneficial.
- (2) Those unconditionally harmful, such as fir, alkalies and poisons.
- (3) Those which might be included among food-stuffs with certain reservations.

The first series comprise water, ghee, milk and honey. To these are added boiled rice, the salt known as *saindhava* and the juice of the pomegranate and the "*amalakam*." The habit of drinking dirty or contaminated water is condemned; yet to-day drinking of tank waters is responsible for the fact that Bengal enjoys the unenviable reputation of being the home of cholera and the cause of all the pandemics of cholera in the world.

The articles of diet which are wholesome and may safely be included in the dietary are various vegetables such as spinach, the meat of the deer, and the flesh of wild game birds, partridge, pigeon, etc.; also the pulses of various kinds. These may, however, become unwholesome through incompatible combinations. Of such, meat should not be eaten with boiled rice prepared from germinating paddy, or with lard, honey, milk, treacle or *mash dāl*. Milk taken with fresh fruits, or salt, flesh of goat and mutton, or with fish and wine, is poisonous. Honey should not be taken in Spring or Summer, or with any substance heated by fire. Ghee kept in a vessel of Indian bell-metal for 10 days should be rejected. Water should never be drunk with melons, for fear of cholera.

Any two oily substances, such as oil and ghee, or honey with either, mixed in equal proportions should not be taken; nor should water be taken after ghee, honey or oil. Things or substances incompatible in tastes should not be taken together. Meat may be suitable for persons of youthful vigour and strong appetite or in those who have become habituated to it.

These suggestions of Susruta have really a sound physiological basis, claimed the author. Nitrogenous foods such as meat should not be followed by milk, whilst milk is curdled by mangoes and acid fruits. Also meat is not well tolerated in hot countries. In one case a patient put on to a chicken diet suffered severely from urticaria. It was found that the chickens were cooked in suet, and when this was changed to ghee, the symptoms disappeared.

The dietaries of Susruta depended on the *tridosha* theory, which the author next explained. The Susruta interpretation of the Vedas, however, was tantric in character, and very difficult to follow. The three fundamental or primary virtues are held to be *sattva*, *raja*, and *tama*. The *sattva* regulates katabolic changes in a physical plane; the *raja* deals with affections in the moral plane; and the *tama* with spiritual matters in the psychic plane. The three states in the physical plane are the three *doshas* and are:—(i) *Vaya*, the regulative or nervous force; (ii) *pitta*, the anabolic or generative process; and (iii) *kafa*, the katabolic or disintegrating process. Unfortunately the *doshas* had

been symbolized in the physical plane as wind, bile and phlegm.

Vaya really corresponded to the sum of the regulative forces, viz., those in the atom, the primitive—sympathetic—brain, and the central nervous system. *Pitta* was used of both bile and metabolism and heat. *Kafa* was the chyle which filled all the interstices of the tissues. Essentially it was cooling in function, surcharging the organism with its own humidity: it might best be interpreted as the effect of the intracellular fluids that regulate the chemical metabolism at cell surfaces. Finally came the *rasa* or lymph chyle, exercising a soothing effect upon the entire organism and contributing to an increased formation of blood and vitality.

The loss of *vaya* is followed by diseases marked by languor and unconsciousness; the loss of *pitta* by impairment of the body heat, digestive disturbances and jaundice; the loss of the *kafa* by dryness, burning fever, thirst, insomnia and febrile disturbances.

Accordingly, diets in disease should be so directed as to contribute to the *dosha* concerned with the disease in question. They could be classified as follows:—

(1) Those acting on the *vaya*, or nervous system. Thus most kinds of fish, which corresponded to the Western idea that fish contained much phosphorus. Nuts, the seeds of such plants as melons, pumpkins and cucumbers are good. The flesh of the pigeon is recommended for facial paralysis. On the other hand, substances which decrease the *vaya*, such as tea, opium, *Cannabis indica*, coffee and walnuts, should be avoided, or only used as brain sedatives at the end of a long and arduous tropical day.

(2) Those acting on the *pitta*, or digestion. Such articles as radishes and cucumbers; the various *dāls*, especially when unhusked, and the coarser varieties as *kesari* and *arrāh*, to stimulate digestion. To correct indigestion articles which decrease the *pitta*, such as ginger, cloves, cardamoms and asafetida.

(3) Finally, those acting on the *kafa*. Articles which increase it are innocuous foods, such as milk, ghee, water and honey. Unfortunately the misinterpretation of the *kafa* as phlegm—which is not Susruta's original teaching at all—has led to the taboo of articles which increase the *kafa* in all respiratory diseases with increased expectoration; thus milk is tabooed in all respiratory diseases, including bronchitis and phthisis. On the other hand, Western Medicine regards milk as an invaluable source of nutrition in phthisis. Great attention is paid in India to articles which increase the *kafa* and are aphrodisiac; such as the milk of the camel, the flesh of the pigeon and sparrow, ghee, honey, *glur*, various wines, and the pistachio nut. Articles of diet which decrease the *kafa* and should be used in febrile, asthenic states are drinks of the lime, lemon, tamarind, etc.; the diluted products of milk, such as whey, milk and water, diluted curds, orange juice and pomegranate juice, sugar-cane as sherbet. Wives who are separated from their husbands are advised to take coriander, in order to remain sexually faithful during their absence. In any catarrhal conditions, such as bronchitis or coryza, all acid and sour articles should be forbidden.

Turning to various invalid diets, rice is partaken of as:—*Gruel*, 1 part of fried rice to 19 of water, *koi*; *peya*, 1 part of fried rice in 11 of water, boiled until the grains are dissolved; *vilepi*, 1 part of fried rice to 9 of water, boiled until dissolved, and then strained. (The use of indivisible or magic numbers for the dilutions, such as 19 and 11 deserve notice.). Barley is taken as gruel mixed with sugar-candy, and lime juice added. Pulses are taken as soups, 1 part to 19 of water, boiled till dissolved, and flavoured with ghee, salt, coriander or black pepper. Such a soup is demulcent and is much used in diarrhoea. Meat extracts were made much as in Western medicine, but flavoured with fennel seeds and black pepper. *Suji chappals* of wheat are much partaken of in the Punjab, and are said to be easily digestible. During convalescence boiled *koi* and old *sabi* rice were much favoured.

Turning to the applications of these diets in different diseases:—

(1) In *fevers* where the *kafa* is affected, the main line of treatment is fasting then to give sherbets, pomegranate juice, grapes, various gruels of rice, fish soups, and finally old *sabi* rice. In Northern India lime juice, gram soup and *suji chappaties* are largely used.

(2) In *nervous diseases*, when the *vaya* is affected, as in epilepsy, etc., fish is given as soup, cooked fish heads, curry: also almonds, pumpkin seeds, and cucumber seeds.

(3) In *dysentery* and *diarrhœa*, the patient, if not too weak, is first made to fast, and then given gruels of barley or fried rice, flavoured with coriander or ginger, pomegranate juice, and *ysufgul*. As convalescence sets in, fine old rice, *dâls*, curries of fish or brinjal vegetables are given; but spices and oil are cut down to a minimum. Goat's milk was sometimes used, and soups made from the flesh of young animals without spices. Milk—being considered to be a laxative—was prohibited. The apple and quince were freely used, and are regarded as constipating,—in contradistinction to Western ideas.

(4) In *constipation* green vegetables, the coarser *dâls*, and fruits—except apples and quinces—are indicated. Meat and rice, being constipating, are cut down to a minimum; whilst a favourite prescription is a glassful of milk taken the last thing at night.

(5) In *indigestion* milk, especially unboiled goat's milk, curdled milk, *kidgeri* and wheaten *chappaties* are given. Ghee, meat, coarser pulses, honey and wine are prohibited.

(6) In any disease associated with *cough*, milk, ghee, rice, and all sour or acid substances are prohibited. Instead, meat,—especially goat's flesh,—eggs, *dâls*, *chappaties* and such drying substances as tea and coffee are recommended.

(7) *Cholera* is usually attributed to drinking water whilst partaking of such raw fruits as melon and cucumber. All food is stopped, and a decoction of aniseed, cinnamon and cardamoms is given,—(rather recalling Dr. Tomb's "essential oils" mixture"). If collapse supervenes raisin or date infusions are given.

(8) In *leprosy*—(with which all varieties of leucoderma and some other skin diseases are confused)—fish, oils for cooking, new rice, meats, onions, garlic, chillies, alcohol, curds, sour articles and sweets are prohibited. Diet should consist of old rice, pulses as *dâls*, bitter curries, green plantain shoots, young neem leaves, and leaves of *punarnava* (*Barhaavia diffusa*). Soaked gram, wheaten cakes and vegetable curries are permissible. Everything should be cooked in ghee, and as much ghee as possible taken.

In conclusion, the author hoped that he had presented an impartial and unbiased exposition of the subject. These ideas were those held by the common people, based upon the sound principle of experience. He had not criticised the *tridosha* theory, but had merely tried to explain its tenets. The Indian patient always asked for detailed instructions with regard to his diet, and it was essential for the medical practitioner in this country to be familiar with his dietary customs and habits.

In thanking Major Acton for his paper on behalf of the Society, Major R. Knowles, I.M.S., spoke of the keen interest which the late Sir Pardey Lukis, I.M.S., had always shewn in the subject. It was one in which we were profoundly ignorant, yet the second question which every Indian patient asked was with regard to his diet. Hegner had recently shewn that a change from a mixed or vegetarian diet to a carnivorous one might eradicate infections with intestinal flagellate protozoa; whilst Castellani considered rhubarb almost a specific for bacillary dysentery in young children. A curious custom which he had observed among the Khasis in the Khasia and Jaintia Hills was to embalm their deceased

chiefs in honey. It was stated that the honey was subsequently extracted and sold, and that the longer it had been in contact with the dead chief, the higher the price which it fetched and the higher its nutritive quality was supposed to be.

Dr. U. P. Basu said that our knowledge of the subject was exceedingly scanty. There were but few written records, knowledge being rather hereditarily handed down from one generation to the next. Certain possible diets were curiously neglected by Bengalis. On the other hand, *moori* and *koi* rice preparations were valued for their sleep-inducing properties in the aged. Milk was in general a substitute for meat, but since the development of present-day urban conditions, and the giving up of Hindu households of their milch cow, milk had become a source of disease, rather than of health. "Every Hindu his own cow" would not be a bad motto.

In reply, Major Acton thanked Dr. Basu for his interesting suggestions. With regard to milk adulteration in India, it was practised on an almost incredible and widespread or universal scale. As Health Officer of Simla he had found that cow or buffalo milk was customarily diluted with three parts of (clean or dirty) water.

Antimony Salts in the Treatment of Leprosy.

In the *Bulletin de la Societe de Pathologie Exotique*, No. 9, 1924, Tournier describes the use of antimony salts by the mouth in the treatment of leprosy. The salt used is "kermes" in doses of one-third to half a centigram in watery solution daily by the mouth. Slight nausea was noted in one of the two cases, but no vomiting nor other sign of intolerance of the drug. Marked improvement was noted in both cases within a fortnight to six weeks, and in a comparatively short time all signs of active disease had disappeared. Both of these cases were of early nodular leprosy. In two other cases of nerve leprosy the same treatment was used, but in addition a course of injections of novarsenobenzol was given intravenously and the results were excellent. Courses of treatment of about two months are advised with periods of rest of about three weeks. The extreme simplicity of the treatment and its freedom from risks of all kinds are accentuated by the author who pleads for a trial in leprosy asylums. He points out that the treatment can readily be combined with the usual treatment by ethyl esters of chaulmoogra oil.

Even taking into account the well known natural tendency for the disease to undergo spontaneous amelioration it would seem to be desirable to give the method a further trial as there are many victims of the disease who are unable to obtain skilled modern treatment to whom an inexpensive drug like kermes would be a great boon if it were found to be effective.

The Aetiology of Sandfly Fever.

WHITTINGHAM makes an interesting contribution to our knowledge of sandfly fever in the *R. A. M. C. Journal* of March 1925.

He defines sandfly fever as an acute specific fever caused by a virus, possibly a leptospira, conveyed to man by the bite of a sandfly. The incubation period is about five days. The disease is characterised by fever of about 3 days' duration, flushed face, suffused eyes, pains in the back and legs and severe frontal headache. Doerr showed that the blood of man is infective only on the first day of the disease. Spirochetes have been reported:—(1) By Couvy in cases of dengue in Beirut in 1921. (2) By Whittingham in cases of sandfly fever in Malta in 1921. (3) By Vervoot and Van de Velde

JULY, 1925.]

in cases of 3 to 5 days types of fever in the Dutch East Indies in 1922. The leptospira found by Wittingham was obtained by blood cultures in Wenyon-Noguchi medium. Morphologically it was indistinguishable from *Leptospira icterohæmorrhagica*, but it was not pathogenic to guinea-pigs. This is a point of doubtful significance as spirochaetes are liable to lose their virulence when cultivated.

Wittingham then raises a most important point which has already been emphasized by Lieutenant-Colonel J. W. D. Megaw, I.M.S., in a paper in the *Indian Medical Gazette* of September, 1923: "Were all the cases investigated at Malta, true cases of sandfly fever?"

Wittingham's points are that sandfly fever varies very much from year to year, and he says that "it is possible that the leptospira isolated was a modified form of that which causes epidemic jaundice modified by passage and perhaps atmospheric condition."

Colonel Megaw's comments on this question were:—"Two independent workers (Couv and Wittingham) have found evidence of spirochætal infection, the one in a disease which he regards as dengue, the other in a disease which he classes as sandfly fever. But a comparison of the charts and descriptions shows that they were dealing with the same disease. The duration of the fever in the great majority of cases in which spirochaetes were isolated shows that it differs in a marked degree from previously observed cases of dengue and sandfly fever. These fevers last less than 8 days in 99 per cent. of all cases while the cases of Couv and Wittingham lasted as a rule 11 or 12 days." "The occurrence of jaundice in some, and the duration of the fever indicate that the disease is a special type of dengue, showing a distinct suggestion of relationship to infective jaundice, the parasite of which is very similar to spirochæte cultivated by Wittingham."

He also pointed out that the disease cycle in Couv and Wittingham's fever was of 9 to 10 days against 4 to 5 days in the case of dengue and sandfly fever.

It is very important that the true nature of this fever should be established, but one thing is certain, it is quite wrong to assume that it is either dengue or sandfly fever. It is much more likely that it is a closely-related disease with affinities to infective jaundice. The whole subject of the dengue group of fevers needs to be worked out in a systematic manner, and if success is to be attained the workers must divest themselves of preconceived ideas such as have so seriously hindered work on the subject in the past. One of these is that any school-boy ought to know how to distinguish between dengue and sandfly fever; another is that as a stegomyia has been proved to carry the virus of dengue and a phlebotomus the virus of sandfly fever, there is no need to consider the possibility of other insect vectors in either case.

A point which remains to be settled is the difference, if any, between the virus of dengue and sandfly fever. Another is the nature of the spirochaetes which have been found in some short fevers by Couv, Wittingham and the Dutch observers. If these are true spirochaetes it is likely that the fevers belong to the infective jaundice group, as the skilled and persistent search of Major Knowles, Dr. Chandler and many other observers has failed to reveal any spirochæte in true cases of dengue. He does not suggest that the spirochæte has been excluded as the possible cause of dengue and sandfly fever, but if a spirochæte be the cause of these diseases, it is not likely to be the one discovered by Couv and Wittingham. The suggestion of Wittingham that his cases may not have been sandfly fever is one of great importance. Coming from him it will have much greater weight than an opinion expressed by a critic of his work. The dengue-sandfly-fever group still remains one of the most interesting elusives of the unsolved problems of tropical medicine.

Reviews.

A TEXT-BOOK OF PRACTICAL THERAPEUTICS.—By Hobart Amory Hare, B.Sc., M.D., LL.D. Nineteenth Edition, 1925. London: Henry Kimpton. Pp. 1061. Price 38s. net.

THIS well-known book has reached its 19th edition and therefore, needs no introduction to our readers. Many additions have been made in the text and the book has been brought thoroughly up to date and it is certain that this new edition will achieve as great a degree of popularity as its predecessors.

The more modern forms of therapy are fully discussed and the practitioner who consults the volume has the assurance that he will be helped to treat his patient "quickly, safely and with comfort."

Excellent illustrations embellish the volume.

THE PRACTICE OF PEDIATRICS.—By Charles Gilmore Kerley and Gaylord Willis Graves. Third Edition. London and Philadelphia: W. B. Saunders Co., Ltd. Pp. 922. Illustrations 150. Price, Cloth 45s. net.

THIS is the third edition of a book which has been reprinted seven times during the past ten years and which therefore has become an established favourite in America. The reasons for its popularity are evident, it is modern but not too modern, it is comprehensive without being encyclopædic, and it caters for the general practitioner rather than for the specialist. Many of the newer text-books are written by a number of experts each of whom presents a subject from his own point of view and in consequence the broader aspects are lost sight of. Dr. Kerley and Dr. Graves are well acquainted with the modern developments in connection with children's diseases, but they interpret these in such a manner that the general practitioner can make use of them in his every day work. The articles on nutrition, infant feeding and the care of the infant are particularly helpful; they are both scientific and practical. It is impossible to review in detail a book which covers the whole range of medicine, but it may be said that there are few subjects with regard to which the medical man will not obtain help and guidance. Of special value are the illustrative cases which are recorded and the numerous excellent prescriptions which are given. The book altogether is one which can be heartily recommended to the doctor and the advanced student.

PEDIATRICS, VOL. IV.—By various authors. Edited by Isaac A. Abt, M.D. London and Philadelphia: W. B. Saunders Co., Ltd. Pp. 1271. Illustrations 218. Price, £2 5s. net.

THIS fourth volume of Abt's Pediatrics maintains the same high standard as its predecessors. It deals with diseases of the circulatory system, ductless glands and kidneys.

It is essentially a work of reference and in no sense a text-book, but the medical man who seeks for help in dealing with one of the many ailments of children will find in its pages the information which he would seek in vain in one of the smaller books. No less than 26 specialists are concerned in the production of this volume and all of them are American.

It is doubtful whether any other country in the world could produce such a work under present conditions; it is certain that there is no single medical man who is competent to write a detailed review of the numerous articles which it contains.

Every large medical library and every specialist on children's diseases will be forced to buy this large and expensive work, the average general practitioner will find it beyond his means to buy it and beyond his energy to study the nine thousand odd pages which go to make up the complete work.

We can only express our mingled admiration and awe at the degree to which specialism has extended in

America. We in this country must be contented to pick up the crumbs which fall from the tables of our more advanced fellow practitioners in another country.

PEDIATRICS, VOL. V.—By various authors. Edited by Isaac A. Abt, M.D. London and Philadelphia: W. B. Saunders Co., Ltd. Pp. 865. Illustrations 373. Price, £2 5s. net.

THE fifth volume has also been received. There are 24 contributors of whom several are well known in the field of tropical medicine. Dr. Victor Heiser contributes a short article on plague, Dr. Carter writes on yellow fever and Drs. Kraus and Mitchell have an excellent chapter on malaria. The chapters on tropical diseases are good, though in some cases inadequate for workers in the tropics. The rest of the volume deals with orthopædic surgery, tuberculosis, hereditary syphilis and various infections.

COLLECTED PAPERS ON BERI-BERI.—By H. Fraser, M.D., D.P.H., and A. T. Stanton, M.D., M.R.C.P., D.P.H. London: John Bale, Sons and Danielsson, Ltd., 1924. Pp. 103.

THESE papers have already been fully reviewed in the *Indian Medical Gazette*. All those who are interested in beri-beri will be glad to have these classical papers in so convenient a form.

ACUTE INFECTIOUS DISEASES.—By Dr. J. D. Rolleston, M.A., M.D. London: William Heinemann (Medical Books), Ltd., 1925. Pp. 376. Price, 12s. 6d. net.

THIS book embodies the experience of one who has had exceptional opportunities of studying the acute infectious diseases. It will be found thoroughly practical and helpful to those who are engaged in medical practice; from the student's point of view the absence of illustrations and temperature charts detracts very much from its value.

Differential diagnosis is not sufficiently dealt with, and on the whole the book will appeal more to the experienced medical man than to the beginner.

THE ADVANCE OF ORTHOPÆDIC SURGERY.—By A. H. Tubby, C.B., C.M.G. London: H. K. Lewis & Co., Ltd., 1924. Pp. xii plus 144, with 31 illustrations. Price 7s. 6d. net.

MR. Tubby is a past master of the craft of orthopædic surgery and anything which he may have to say of the present-day work is certain to be interesting. This little book consists of six articles reprinted from the *Clinical Journal*, dealing with the value of modern radiological technique in orthopædic work, certain recently described conditions, such as Leggs', Köhler's and the Osgood-Schlatter's disease, and static and postural deformities due to asymmetry of limbs or trunk, a branch in which the author's ingenious methods of measurement have thrown light on the origin of the deformities observed. The later chapters deal with the reconstructive surgery of paralysis, arthroplasty—with which operation his own results have been better than those of the majority of surgeons,—and re-education of cripples. The whole forms an interesting series of articles appealing to the surgeon who specialises in this branch.

We noticed an amusing misprint; Professor Putti is represented as belonging to Boulogne instead of to the Italian city which is known the world over for its excellent brand of sausages.

PYE'S SURGICAL HANDICRAFT.—Edited and largely re-written by W. H. Clayton-Greene, C.B.E., F.R.C.S. (Eng.), Surgeon to St. Mary's Hospital. Ninth Edition. Bristol: John Wright & Sons, Ltd., 1924. Pp. 619. Price, 21s. net.

THIS is a book which has for so long held an accepted place in surgical literature that it has passed the stage of being criticised by a reviewer in regard to its scope and utility. It has for many years been a trusted

guide to the house surgeon and young practitioner, and as the years go by and the subject grows, the book tends to increase steadily in size. To the eye it looks only a trifle stouter, but if we mistake not the paper is thinner and the printing closer than of old. The present edition contains in its 619 pages a mass of information which it will take the student a long time to master, yet it cannot be said that it contains any superfluous matter. We are informed in the preface that many alterations and additions have been made, but we are not told where to look, so that without a laborious comparison with the previous edition it is not possible to appraise the changes which the volume has undergone. A few small defects struck us however. The work of Kanavel on the treatment of palmar supuration has rendered obsolete the methods of treatment here described and the account of the causation of shock is not in accord with modern views. Delayed chloroform poisoning is not mentioned, nor do we find any reference to the immense value of glucose in rectal irrigation, now almost universally used. The few paragraphs on the treatment of gonorrhœa in which injections with a small syringe are advocated, whilst Janet's irrigations are reserved for obstinate cases, is of very doubtful value. In the urological section there are several recommendations with which we disagree; the use of cocaine in the urethra has long been regarded as dangerous and since other equally efficient agents are available, we would prefer to keep to the traditional teaching. The use of a 1 in 40 solution of lysol to cleanse the glans penis would be very painful and is surely an oversight. The Beniqué pattern of urethral sound is now so commonly used that a figure of it should be given.

THESE are small points, however, in a book of such a high general level of excellence and as a set-off it gives us great pleasure to note the admirable articles on the special departments contributed by specialists, particularly that on the teeth by Mr. Bennett, the detailed directions for extraction of the various teeth are the best we remember to have met with in a work of this kind. We have great pleasure in recommending this book to students and practitioners as heartily as ever.

A MANUAL OF DISEASES OF THE NOSE, THROAT AND EAR.—By E. B. Gleason, M.D., LL.D. Fifth Edition. Philadelphia and London: W. B. Saunders Co., 1924. Pp. 660, with 212 illustrations. Price, 20s. net.

THIS fifth edition of an excellent book we welcome with great pleasure.

THIS edition has been enlarged and brought up to date.

DR. Gleason's book is most eminently practical. Methods of examination of the nose, throat and ear are discussed in a clear and practical manner. A description of the anatomy of the parts is followed in each case by a lucid and concise account of the diseases, their diagnosis and treatment. The description of the more common operations is admirable and makes very clear reading.

THE work is well illustrated and a considerable number of the engravings are original or drawn from dissections made by the author. There is also at the end of the book a list of formulas which should be found extremely useful.

THE book is an excellent one to give the student of this special branch of medicine a comprehension of its field and as it is written with exceptional clearness and simplicity, it will prove helpful to the general practitioner and should occupy a useful place in his library.

THE BACTERIOLOGY OF FOOD.—By Cuthbert Dukes, M.D., M.Sc., D.P.H. London: H. K. Lewis & Co., 1925. Pp. x plus 180, with 25 illustrations. Price, 7s. 6d. net.

THIS is an excellent hand-book on food bacteriology in which all available information regarding the subject from the hygienic, medical, agricultural and industrial points of view is collected and combined in one volume.

The chapters on milk and milk products particularly have been very well written and contain all the information which students of public health ought to possess. The whole subject is written in a style very attractive and interesting, and in a way which will appeal not only to students preparing for the University qualifications but also to those of the lay public who take an interest in this all-important subject of food bacteriology.

A slight error has crept in on page 28, on the subject of filtration. It is stated that the water is filtered at the rate of about 1 inch per hour; the usual rate is about 4 inches per hour.

THE USE OF FISH FOR MOSQUITO CONTROL.—Issued by the International Health Board of the Rockefeller Foundation, New York, 1924. Paper-covered brochure of 120 pp., with 65 illustrations.

This admirable brochure should be in the hands of all engaged in anti-malarial campaigns. The book is not on sale, we understand, but is for general distribution to those who may be especially interested in or concerned with such work. Fish as an agent for the control of mosquitoes have been tried in a desultory way on every continent and in many cities, but only in the United States and South America has definite scientific progress been made in the subject. Yet, if a body of water in which mosquitoes breed is permanent, is not chemically polluted, nor obstructed by vegetation, there seems to be no reason why the right kind of fish should not be exceedingly useful in mosquito control. Further, the method is biologically sound, and its effects cumulative, once the fish are acclimatised.

In South America the use of fish against the yellow fever mosquito was a complete success. Here the water containers used were readily accessible, were easily stocked and at all times subject to human control. Similar conditions exist in limited natural areas not too large to be successfully patrolled by men. In the Mississippi it was shewn that in bodies of water cleared of vegetation, properly edged, and amply stocked with the right fish, no mosquito larvæ survived. As a consequence the malaria index went down.

It is emphasised however that floatage and vegetation must be cleared or the fish will be unable to reach the larvæ. Also the importation of fish from other regions has frequently been a failure, not so much from difficulties in transporting them as from their failure to become acclimatised. It is better to use fish indigenous to the region concerned. Experience has shewn that small fish belonging to certain widely distributed families, prominent among which is the top-minnow, are likely to give the best results for *Anopheles* control; for *Stegomyia* control bottom-feeders of various kinds are preferable.

Within limits, perhaps not so narrow as may be supposed, the method is ready to take its place as a recognised auxiliary means of both yellow fever and malaria control.

The chapters in the book deal with biological methods of combating insects, the functions of fish, the requirements of fish as mosquito destroyers, a historical survey of the evolution of the method, and details of fish control in different countries, and the advantages and limitations of the method. At the end is a very complete bibliography of the subject. The work in India of Southwell, Fry, Chaudhuri, Sewell and Wilson is described.

AN X-RAY ATLAS OF THE NORMAL AND ABNORMAL STRUCTURES OF THE BODY.—By A. McKendrick, F.R.C.S. (Edin.), D.P.H., F.R.S.E., and C. R. Whittaker, F.R.C.S. (Edin.), F.R.S.E. Edinburgh: E. & S. Livingstone, 1925. Pp. 222. Price, 25s. net. Postage, 9d.

In this atlas, according to the authors, "an attempt has been made to provide a series of radiograms illustrating the normal and abnormal structures of the body, and also the more common injuries and diseases."

A feature of this work is the publication of radio-

grams showing the different appearances presented by an alteration of the focus point, sixty radiograms have thus been allotted to a study of the normal joints and limbs.

The series of skiagrams representing the joints of the limbs is followed by a series representing the condition of the joints at the age of ten years, and giving the dates of the ossification of the epiphyses.

The letterpress and reproduction of skiagrams leave nothing to be desired and reflect great credit on the publishers.

Radiologists and surgeons will find this volume a very valuable addition to their libraries and an extremely useful guide in X-ray diagnosis.

MANUAL OF PSYCHIATRY FOR THE MEDICAL STUDENT AND GENERAL PRACTITIONER.—By Phil E. Bowers, M.S., M.D. London and Philadelphia: W. B. Saunders Co., Ltd. Pp. 365. Price, 18s. net.

THERE is in this book much to commend it, but American laws and methods of dealing with insane and borderline cases differ so widely from those existent in India that as a handy book of reference it can hardly be recommended to the student or practitioner in India. For the legislator, social worker, educationalist and others of that ilk a perusal of its pages, besides being a useful and pleasant means of filling up a leisure hour will provide much food for thought and knowledge which they might usefully apply to the performance of their duties in their various spheres.

In a book of this type it is naturally impossible to deal fully with every aspect of the subject, but one cannot help feeling that a perfect balance has not been maintained throughout. Some chapters are admirable, others leave one with the sense of a task incomplected, while one or two again seem to err on the side of excessive and unnecessary detail.

The classification adopted is a slight modification of that of the American Psychiatric Association and differs very greatly from the official classification in India. This, however, is a matter of small moment really as the clinical entities dealt with in the text are readily recognisable by one with any knowledge of the subject.

It is interesting to see the prominence given by Dr. Bowers to the physical side of such conditions and the importance he attaches to heredity and environment in their production.

His remarks on endocrine therapy are very interesting and practically the same as those quoted on page 14 of the February supplement of the *Indian Medical Gazette*, i.e., he sees great possibilities before it but recognises that further experience is necessary before any definite statement can be made regarding its efficacy.

The book can be thoroughly recommended to those interested in psychiatry or whose activities be in the spheres already indicated.

AIDS TO PSYCHIATRY.—By W. S. Dawson, M.D. (Oxon.), M.R.C.P. (Lond.), D.P.M. London: Baillière, Tindall & Cox, 1924. Pp. viii plus 309. Price, 4s. 6d. net.

THE "Aids to Psychiatry" by Dr. W. S. Dawson, is one of the best of this series. The study of psychology is often neglected in the physiological course, and here we get a very accurate précis of the whole subject. Freud's theory, which is difficult to understand from his own writings, is very ably condensed into nine pages of the book. The modification of this theory by Jung is very accurately and fairly described by the author. We would like to have seen greater stress laid on the neuroses, i.e., actual and psychoneuroses, as regards their causation by endocrine defects which raise the excitability of the nervous system and help in exaggerating the various anxieties and obsessions seen in these mental states. The different types of insanity are well described, and this should be of great use to the practitioner. We would strongly recommend this book

as giving a very fair and accurate picture of these mental states in as short a compass as possible.

GENERAL SYSTEMATIC BACTERIOLOGY.—By R. E. Buchanan, Ph.D. Baltimore: Williams & Wilkins, 1925. English Agents, Messrs. Baillière, Tindall & Cox: London. Pp. 597. Price 30s. net.

THE present volume is the first of a proposed series of monographs in the general field of systematic bacteriology. Systematic bacteriology has two principal aims or functions which are of importance to the teacher and the investigator. The first of these aims is the presentation in graphic form of our present conception of the phylogeny and of the relationship of various groups of bacteria. The second is to give a greater degree of stability to names used for particular groups of organisms and to prevent unnecessary nomenclatural confusion in the literature.

Bacteriologists can be divided into at least two classes; each views the subject from his own particular angle. On the one hand the interest of the botanist centres on the organism itself, its life phenomena and its pedigree, whereas the pathologist, the agricultural chemist, etc., view it from the point of view of the changes which it produces in tissues and other media. Each demands a classification which fits in with his own particular point of view.

The first chapter of the present volume gives a short account of various classifications of bacteria that have from time to time been adopted; from Mueller's classification of the Vermes (1773), which included the bacteria, down to the classification according to Bergey (1923). One cannot help being struck by the absence of the great names familiar to the medical bacteriologist from the headings of these classifications.

The second chapter discusses various codes of nomenclature and the suitability of their application to bacteriological nomenclature, and is concluded with a report of the suggestions and recommendations of the Society of American Bacteriologists with regard to classification and nomenclature.

Chapter III, which constitutes more than two-thirds of the volume is an alphabetical list of the names which have been applied by various authors to designate sub-genera, genera or higher groups of bacteria. One wonders how many volumes would have been occupied had the author treated in the same way the various names applied to species.

The book will prove valuable both to the potential offender and to the unfortunate sufferer in the matter of bacteriological nomenclature; the former will do well to study Chapter II, carefully so that he may not add to the confusion, the existence of which Chapters I and III demonstrate; the latter will find Chapter III extremely useful when he wishes to discover what is really meant by any of the loosely-applied generic names with which the literature abounds.

This volume forms a useful addition to the library of any medical bacteriologist and is almost indispensable to the systematic bacteriologist who wishes to be up to date in the matter of nomenclature.

PATHOGENIC MICRO-ORGANISMS.—By William Hallock Park, M.D., Anna Wessels Williams, M.D., and Charles Krumwiede, M.D. Eighth Edition. London: Baillière, Tindall & Cox, 1925. Pp. x plus 811. Plates 9. Figs. 211. Price 30s. net.

THIS well-known book has been thoroughly revised and brought up-to-date; it is now in its eighth edition. The writers have succeeded in producing a manual which is not merely a collection of facts but is a well-balanced and readable book in which the student and practitioner will find all that is of importance in the science and practice of bacteriology. One says bacteriology, because, although the scope of the book includes the allied sciences,—protozoology and mycology,—it is written by bacteriologists mainly for the use of the student and the health officer.

However, the more important protozoa and yeasts have not been neglected.

The book is divided into three parts; the first part deals with the classification and general description of the various groups of pathogenic organisms, with practical laboratory methods and with immunology; the second part, which constitutes about half the book, deals with the known pathogenic organisms; and finally the third part, which is headed "Applied Microbiology," deals with the practical application of the science and includes chapters on such subjects as vaccine and serum therapy, examination of water disinfectants and so forth.

It is in every way an excellent book and one that we can thoroughly recommend both to the laboratory worker and the practitioner; it is also extremely useful as a text-book for the student. The book is printed in large, clear type, on good paper and is freely illustrated with very well reproduced photographs and diagrams.

Annual Reports.

NOTES ON VACCINATION IN THE CENTRAL PROVINCES AND BERAR FOR THE YEAR 1923-24. BY LT.-COL. T. G. N. STOKES, M.B., I.M.S. NAGPUR: GOVERNMENT PRESS, 1924. PRICE RE. 1.

THERE were 37 assistant superintendents of vaccination and 301 vaccinators on duty during the year in this province; the total number of vaccinations performed being 5,01,398 as against 4,29,291 in the previous year. Colonel Stokes notes, however, that large numbers of unprotected children are still to be found both in municipal towns and villages, and that the number of operations performed by individual vaccinators is still, in general, far below the standard. Now that the district councils and local boards have shouldered the responsibility for the work, matters may improve. The number of re-vaccinations, was unsatisfactory, and in spite of a government press communiqué and in face of a considerable amount of small-pox, the state of affairs with reference to re-vaccination is bad. A villager assaulted a vaccinator in one district but was acquitted on trial, principally because vaccination is not compulsory under the law. Two other vaccinators were recently assaulted whilst in the execution of their duty, and one such case is still on trial. Colonel Stokes comments that if vaccinators can be obstructed in the performance of their important duties with impunity, matters are not likely to improve. The civil surgeon of Amraoti reports that in the village of Sirasgaon not one child was vaccinated during the year, but fails to give the reason for this. Report after report emphasises the necessity for compulsory vaccination, and proposals for the introduction of compulsory vaccination in rural areas are now under the consideration of government.

The cost of the department during the year was Rs. 1,96,210, the average cost of each successful vaccination being Rs. 0-6-10. The glycerinated lymph issued from the institute at Nagpur continued to be satisfactory; 185 calves were operated on during the year and 6,450 grammes of lymph obtained equivalent to 5,60,480 doses. In primary vaccinations the insertion success rate is reported to have been 92 per cent. as against a figure of 48 per cent. for re-vaccination. The number of deaths recorded from small-pox during the year was 420, but Colonel Stokes considers that this does not represent the true state of affairs, since several reports state that the disease has made serious havoc in different districts. "It will be seen" he writes, "that vaccination work is being neglected both in municipal towns and rural areas, mainly owing to the apathy and indifference

of the local bodies. As this is the fifth year since the last big epidemic of small-pox and there is every likelihood of the disease assuming serious proportions, I would very strongly urge these bodies to adopt drastic measures." The suggestion made to train schoolmasters as vaccinators is an impossible one, whilst no advantage would be gained by handing over the work in municipal areas to dispensary assistant medical officers. Apparently the Central Provinces are waiting for the next big epidemic before their local and municipal authorities really set their house in order.

ANNUAL RETURN ON VACCINATION, BIHAR AND ORISSA, FOR THE YEAR 1923-24. By LT.-COL. W. C. ROSS, M.B., CH.B., D.P.H., I.M.S. PATNA: SUPDT., GOVT. PRINTING, BIHAR AND ORISSA, 1924. PRICE 10 ANNAS.

It is curious how unanimous are all recent vaccination reports from different provinces. "I do not consider," writes Colonel Ross, "that small-pox can be effectively dealt with and stamped out unless vaccination is made compulsory throughout the Province, and I would recommend that the Vaccination Act should be modified so as to extend the age within which vaccination is required to one year, and should be generally enforced; also that vaccination should be free." This summarises the situation—as far as we can gather—for every province in India. In a "successful" year at present in any province in India the number of persons vaccinated is about 23 per mille, which is considerably below the average birth rate of about 38 to 39 per mille. As a result the Indian population is becoming year by year less protected against small-pox, and the experiences of at least Bengal and Bihar and Orissa in 1924-25 are that epidemic small-pox is increasing. The present Acts are unsatisfactory in many ways; in report after report it is suggested that vaccination should be made compulsory, at least in the rural areas, whereas it is now voluntary. Further, the Indian parent is averse to having his child vaccinated under the age of six months, and many different Directors of Public Health in the Provinces suggest that this difficulty can be easily met by raising the age within which vaccination should be enforced, to one year. We read in several reports that such matters are "under the consideration of government"; we trust that this does not mean that decision will be deferred to the Greek calends; otherwise small-pox may soon take the place which epidemic plague now holds in India.

The inspecting staff during the year consisted of the Director of Public Health, three Assistant Directors of Public Health, 20 district inspectors and 69 sub-inspectors. In municipalities and in Puri district vaccination was done by paid vaccinators; otherwise vaccination was carried out under the licensing system, except for the employment of paid vaccinators by district boards; and 1,088 licensed and 228 paid vaccinators were on duty during the year. The total number of vaccinations performed was 1,043,264 as against 1,002,889 for the previous year. The success rate was 97.25 per cent. in primary operations in municipalities and 49.94 per cent. in re-vaccinations. It is noted that Patna shewed a decrease of over 1,000 vaccinations, whereas in the Native States where both vaccination and re-vaccination are practically compulsory, matters are very satisfactory. During the year the number of children under one year of age available for vaccination was 1,034,163, of whom 3,75,127 were successfully vaccinated. More than half the vaccinations performed are on children of more than one year of age, and civil surgeons and assistant directors of public health are unanimous in attributing the opposition to vaccination of parents more to the age of the child than to the actual operation of vaccination itself.

During the last ten years the deaths from small-pox in the province were 95,628, and Colonel Ross notes the tendency of the disease to recur in cycles

and anticipates a severe epidemic in 1926 or 1927. "The constant and considerable mortality from small-pox," he writes "is, in my opinion, a complete demonstration both of the insufficiency and of the inefficiency of the existing arrangements for vaccination."

The Vaccine Depot at Namkum supplied the province with vaccine lymph throughout the year, and 5,357,025 doses were manufactured, whilst a large reserve supply is in hand. The average cost of the vaccine works out at 0.91 pies on gross expenditure and 0.34 pies on nett expenditure, when receipts are taken into account. During the year adult animals in place of calves were used to some extent to supply the lymph, as they are cheaper in the long run. The cold storage plant gave considerable trouble, and a duplicate engine is required. Experiments were made in the use of 0.05 per cent. iodine added to the lymph to purify it, and were very satisfactory; after plating such treated lymph no bacterial colonies grew. The total cost of the department during the year was Rs. 1,52,980; or 2 annas 4 pies per successful vaccination.

HEALTH DEPARTMENT, CIVIL AND MILITARY STATION, BANGALORE; ADMINISTRATION REPORT FOR 1923-24. POWER PRESS: BANGALORE, 1924.

THIS report by Dr. S. Amritaraj, L.R.C.P. & S., D.P.H., Health Officer, Bangalore forms part of the Municipal Commission, Bangalore's annual report for 1923-24, and tells of continued progress. The birth rate was 38.35 per mille, and slightly lower than in previous years; but the mortality rate, 34.03, shewed considerable improvement on the figure of 39.99 for 1922-23. Deaths from tuberculosis numbered 313, and the disease is apparently on the increase in the station; amongst the Mahomedan community it is to be noted that deaths from tuberculosis are four times as common among women as among men, as a result of their close confinement and the purdah system among them. Malaria accounted for 1,628 admissions to hospitals, and the attendance of 12,233 out-patients. Small-pox was also rather prevalent, 182 cases with 52 deaths; but the incidence of plague—84 attacks with 63 deaths—was the lowest recorded for the last 25 years. Infantile mortality for the year was 306.9 per mille, and Dr. Amritaraj comments on the steady rise in price and deterioration in quality of the milk supply; "every year the milk problem is getting more and more acute." How lightly the courts deal with offences under the public health acts is shewn by the fact that in 1,402 prosecutions fines amounting to only Rs. 1,966 were imposed.

Medical inspection of school children was continued throughout the year, and dental caries, nasal catarrh and chronic bronchitis figure largely in the returns received. Antirabic treatment was given by the Health Officer to 65 persons, of whom one died, a child severely bitten in the lip. The chief public health event of the year was National Baby Week in January 1924, which was very successful. The maternity and child welfare work was expanded during the year; two pre-maternity wards and an emergency labour room were added to the Thimmiah Road centre, and four new welfare centres opened in Fraser town, Knoxet, Shoolay and in the Peninsular Tobacco Co.'s works. The progress of maternity welfare work in Bangalore is shewn by the statement that some 33 per cent. of all births which take place in the station are now attended by qualified midwives, and by the fact that the number of untrained practising dais is going steadily down.

ANNUAL REPORT ON THE MEDICAL AND HEALTH DEPARTMENT, MAURITIUS, 1923.

THE annual health report of the island of Mauritius, which is so largely an Indian colony, is always of interest. The area of the island is 720 square miles,

and its population 3,81,678, its density being very high, some 530 persons per square mile.

The birth rate for the year was 36.8 per mille, and the death rate only 28.5 per mille as against an average figure of 42 per mille for the preceding quinquennial period. The chief reduction in mortality has been in malaria, which caused only 1,979 deaths in 1923 as against 3,526 in 1922. There can be no doubt that Mauritius is deriving great benefit from the vigorous anti-malarial campaign which was started three years ago by the health authorities and has since been pushed forward unrelentingly. After malaria, the next two principal causes of deaths were pneumonia and broncho-pneumonia, whilst infantile diseases accounted for 1,026 deaths. The infantile mortality rate was 139.4 per mille, a figure greatly below corresponding figures for India. The chief causes of the infantile mortality are venereal diseases, congenital debility, premature births, improper food and methods of feeding. As usual mortality among infants less than one year old was greater among male infants, 1,058 deaths, than amongst females, 877 deaths. During the year the training of midwives was put on an efficient basis, and it was arranged in 1924 to provide Government qualified midwives in every district and township. Four crèches were at work during the year, one of them on the Riche-en-Eau Sugar Estate endowed by the principal owner of the estate.

Hospital and dispensary attendances totalled 82,326. The death rate from malaria was 5.1 per mille as against 8.6 per mille for the quinquennium 1919-23. The spleen index, on an examination of 12,925 school children was 15.6 per cent., and the endemic index on 5,368 children examined, 9.4 per cent. There were 1,192 admissions for influenza with a case mortality, however, of only 4.4 per cent. Dysentery is not a notifiable disease, but caused 379 admissions with a case mortality of 6.3 per cent. Leprosy is also not a notifiable disease, although lepers are numerous in the island, and there were only 37 inmates in the St. Lazare leper asylum. Moogrol and "Oscol" stibium are on trial in treatment. Plague, which was introduced into the island in 1899, caused 118 deaths in 1923, and was endemic all the year round in Port Louis. Despite a vigorous rat campaign, and the destruction of 83,361 rats during the year, it is impossible to exterminate plague in the island; there are many dilapidated old wooden buildings, much overcrowding, insanitation and rat-ridden grain godowns. Educational propaganda is called for, and cinema films dealing with malaria, flies and rats have been ordered. The housing question is acute, and many of the recently erected houses do not satisfy the minimum health requirements: "housing in Port Louis and its suburbs, in populous towns, villages and hamlets is absolutely wretched." A good start has been made under Sir Hesketh Bell, at the model village at Cassis. The construction of this village has provided a mine of information with regard to the best type of materials to be employed in such work. There are 121 model cottages and lodges with 460 inmates.

Cancer accounted for 87 admissions to hospital with 9 deaths. The venereal disease problem is a very serious one, as most cases are concealed, and it is proposed to open a special venereal clinic in the near future. The mortality among women in childbirth is 16.4 per thousand live births,—a regrettably high figure due to dirt and ignorance. The commencement of a new midwifery and child welfare society, however, may improve matters. Pulmonary tuberculosis accounted for 959 admissions and other forms of tuberculosis for 979; and it is hoped to shortly make the disease notifiable, when some measure of its actual incidence in the island will be obtained. The number of persons certified insane was 708, and there were 194 admissions to the lunatic asylum. At the port of Port Louis, 203 sailing craft and 30 steamers were dealt with during the year by the health authorities. Improvements in the hospitals include bringing the Civil Hospital radium and

X-ray plant up to date and also purchasing an X-ray plant for the Victoria Hospital.

The water-supply in some of the districts is good, but in others is bad or inadequate. That of Port Louis is largely derived from Grand River North West and Bathurst Canal, and both these sources of supply are unfit and unsafe. A chlorination plant has been installed at the former, and it is hoped to replace the crude, impure water which 95 per cent. of the inhabitants at present drink by filtered, chlorinated water. Piped supplies are being introduced in many of the country districts.

The milk supply is unsatisfactory; milch cows have been imported by government, and up-to-date stables erected at Curepipe; the supply sent to the Victoria Civil Hospitals being good. A scheme for a central milk distribution centre and a supply of pasteurised milk is being considered.

Dr. T. H. Gilchrist's main report is supplemented by several interesting subsidiary reports. Dr. C. H. Yeager reports on the hookworm campaign. Special measures were taken in Moka district. The general infestation rate was 62.5 per cent., and Rs. 29,702 was spent on the campaign during the year, 12,540 persons being treated. Up to the end of the year 5,780 pit latrines had been constructed in the island; 55 lectures were delivered to audiences totalling 8,840, and the cinema film "Unhooking the hookworm" has been ordered.

Dr. J. B. Kirk contributes a special review of health conditions in Port Louis. The death rate, 34.1 per mille, shews a marked improvement on the figure of 42.6 per mille for 1922. The year saw the entire re-organisation of the sanitary staff, a new special anti-malaria department being created, and special classes of instruction held. Government took over night soil conservancy from the Roche Bois Manure Co.; a policy of efficient removal on alternate days was found to be more satisfactory in results than to attempt a daily service with an insufficient staff. The scavenging of the town is still unsatisfactory, as most of the garbage is burnt in the open. A special type of fly-proof latrine was introduced, and a regular supply arranged for with a government contractor; the regular supply of latrines of this pattern to householders and business firms has been commenced. In the extra-urban area pit latrines are being introduced. Anti-malarial measures were conducted vigorously throughout the year; in this connection it is interesting to note that Mauritius is unlucky enough to have not only *A. culicifacies* and *A. maculipalpis*, but also *A. costalis*, the great malarial carrier of Africa. Cactus clearing forms an important part of the anti-malarial measures. In anti-plague measures 6,029 persons were inoculated and a beginning made of rat-proofing of houses in the town. In one instance where premises were fumigated by burning sulphur in open burners in a shop, it was found that rat fleas had remained unaffected, and the technique of fumigation has had to be revised and improved. "Glue boards" have been found useful in the anti-rat campaign; these boards catch not only the rats but their fleas as well. They were introduced by Dr. Balfour and are coated with a varnish made from linseed oil and resin.

Of the state of the central market in Port Louis, Dr. Kirk writes in a strain of despair.—The place is haunted by many dogs, though fortunately Mauritius is so far free from rabies. The meat market is so bad that nothing less than its complete reconstruction would make it satisfactory. "Taken as a whole the central market of Port Louis is of no credit to the municipal corporation, either from a hygienic or aesthetic point of view . . . the subsidiary markets reflect faithfully all the insanitary features of the central market, but on a smaller scale." Some thousands of kilos of foodstuffs were seized by the sanitary authorities as unfit for consumption and either burnt or dumped into the sea. The milk supply is bad and has given the department constant anxiety. (One of the most curious features of Indian life is that the ordinary householder should prefer to buy one part of milk

diluted with three parts of dirty water at about 6 seers to the rupee, rather than pure milk without water at 3 seers to the rupee). Anything up to 60 per cent. of samples analysed were found to be "sophisticated." A test case was taken into court against one milk vendor, who was fined, but no improvement followed.

In the report on school medical inspection, Dr. F. L. Keisler notes that there has been marked improvement in malaria incidence, and also in hookworm infestation. Most of the schools, however, are old converted private residences and not really suitable in construction. Scabies is rather prevalent and measures should be taken to segregate infected children.

The bacteriological laboratory under Dr. L. G. Barbeau records a year of heavy routine work. A case of intestinal coccidiosis was encountered during the year, the oöcysts in the faeces being apparently those of *Isospora hominis*; 385 samples of foodstuffs were chemically analysed, also 189 specimens in connection with medico-legal work.

ANNUAL REPORT OF THE GOVERNMENT CINCHONA PLANTATIONS AND FACTORY IN BENGAL FOR THE YEAR 1923-24. BY C. C. CALDER, OFFICIATING SUPERINTENDENT. CALCUTTA: BENGAL SECRETARIAT BOOK DEPOT, 1924. PRICE 7 ANNAS.

THE year was more or less a normal one, and though the rainfall at Mungpoo was defective for the second year in succession, improved methods of cultivation have kept up the yield of cinchona. All extensions at Mungpoo have been planted on narrow contour terraces, and with improved methods of manuring and shading it has now proved possible to cultivate cinchona on slopes. Only sufficient plantation bark to meet provincial requirements was put through the factory, the balance required being taken from imperial stocks of Java origin. The present bark agreement does not terminate until 1928, hence only the minimum amount of local bark is being cropped. The factory is capable of turning out 55,000 lbs. annually, but with the shortage of water-supply during the year could only be run for 250 days.

The quinine used in India under present conditions is but a fraction of what could be usefully and remuneratively employed, yet in spite of this the accumulated stocks are insufficient for any all-India intensive anti-malarial campaign. Reports of a world shortage of quinine, which have frequently appeared in the press, fail to distinguish between an actual shortage of supply and a shortage of purchasing power. At present the supply is in excess of the demand. "Prices are still largely under the control of the quinine ring . . . many people simply do without quinine . . . the hoped-for fall in price has not materialised."

At Mungpoo the acreage under cultivation was increased by 150 acres, whilst 113 acres were cut, giving a yield of 2,15,366 lbs. At the end of the year there were 937 acres under cultivation. At Rungbee a young plantation, the result of the selection of a high grade tree for planting, promises to give a species with a high quinine yield,—much better than what is obtained with imported Java seed. At Munsong a hailstorm caused considerable but fortunately localised damage. 140 new acres were planted and 148 acres cut, giving a yield of 4,36,086 lbs. The total acreage at both plantations works out at 3,055 acres.

At the factory the total production of quinine sulphate, both provincial and imperial, was 43,264 lbs., and the total of all products 56,822 lbs. The average cost per lb. taken over a series of years was 3.6 annas for Mungpoo bark and 2.7 annas for Munsong bark. The year's expenditure for both plantations was Rs. 2,09,697, but the actual cost of the harvests was Rs. 1,28,296 as against quinine and similar products manufactured worth Rs. 4,99,395 at the present market rate of Rs. 26

per lb. The amount of cinchona febrifuge sold was 12,478 lbs. and the selling rate from Rs. 8 to Rs. 10 per lb. At the end of the year 3,55,081 lbs. of bark were in hand requiring to be worked up.

In addition to cinchona, about 47,500 *ipecacuanha* plants were raised from seed for planting in a new nursery placed some 500 feet higher than the old beds, in the hope of avoiding the evil effects of excessive daily fluctuations of temperature on the plants. Already 3 lbs. of emetine have been extracted, and this Indian emetine is now on trial. The cultivation of *digitalis* is also being continued.

THE ROCKEFELLER FOUNDATION. ANNUAL REPORT FOR 1923: NEW YORK, 1924.

THIS report like its predecessors fills us with admiration tinged with envy, especially in the section which deals with medical education. The bountiful aid which is given to China for the purpose of developing medical education has been continued and this will doubtless bear excellent and abundant fruit in the course of time. Up till now the atmosphere which is needed is still lacking in China and it has been necessary to carry out a campaign for the purpose of educating Chinese students in an appreciation of the value of modern scientific medicine. There are only 53 students at the magnificent and lavishly-equipped Peking Union Medical College.

If only the eyes of the Division of Medical Education would turn towards India and realise the vast needs of this country for a campaign of improvement in medical education there might be wonderful results which could be obtained in a few years instead of the decades which will be needed in the case of China.

The activities of the International Health Board are vast, but here again India is left comparatively in the cold. Can it be that India is supposed to be in less need of help than other countries? Or is it that the Government of India is too proud to appeal for a share of the bounties which are extended to other parts of the world?

Whatever be the cause it is earnestly to be hoped that the Rockefeller Institute will be induced to extend its activities to India not merely in the interests of this country but also because there are good reasons to believe that the conditions for solving the remaining great problems of disease are more favourable in India than in any other country in the world.

Not only is there a great wealth of material, but also there is a large number of well-trained medical men who are capable of taking part in the work of research.

KASHMIR C. M. S. MISSION AND KASHMIR STATE LEPER HOSPITAL. ANNUAL REPORTS FOR 1924. MYSORE: WESLEYAN MISSION PRESS, 1925. PRICE 4 ANNAS.

THE work of the celebrated mission hospital at Srinagar continues to increase, and the year saw 37,151 attendances in the out-patient department, 1,994 in-patients and 5,501 surgical operations. Lady Reading, in a note made after her visit to the hospital in October, speaks of "the efficiency of the arrangements and the splendid work done by Dr. Neve and his staff." Not only is there a large volume of work done at the hospital; medical aid is also taken into the villages, where from exposure to cold and wet, and of digestive disorders owing to a diet consisting almost entirely of rice and Indian corn.

During the year no less than 496 operations were performed for entropion and trichiasis. Pulmonary tuberculosis, once very rare in Kashmir, is now rampant, and the problem is one which demands vigorous State action. Surgical tuberculosis is also very common; there were 73 operations for tubercular glands and most of the amputations were for septic tuberculous joint

disease. Appendicitis, Dr. Neve notes, is uncommon, cancers—except for *kangri*-burn carcinoma—are rare, but sarcomata relatively common. The small number of injury cases dealt with is due to the absence of factories, railways, etc.; but 17 cases of persons mauled by bears were admitted. In the late autumn an outbreak of cholera in the west end of the valley constituted a menace to the health of the whole valley; and there were more than a hundred cases with a 70 per cent. mortality.

Financially the hospital ended the year with a deficit. Owing to Dr. Vosper's transfer to Peshawar the proceeds of a large private practice, first instituted by Dr. E. Neve and later carried on by Dr. Vosper, which are all given to the support of the hospital, were lost. Also the creation by the State of a Directorship of Medical Services and of a whole-time residency surgery will deprive the hospital of another Rs. 2,500 per annum. Rs. 10,300 had to be withdrawn from invested funds. We trust that philanthropists will not be slow in recognising the needs and claims of Dr. Neve's splendid work.

In the leper hospital, which is under the State, there were 215 in-patients during the year, whilst a grant of Rs. 25,000 has been obtained for the building of a new children's home, which will house segregated children. In former times the outlook with regard to the treatment of leprosy was exceedingly gloomy. To-day, Dr. Neve wonders whether the pendulum has not swung too much the other way; in early cases the use of the ethyl esters will lead to improvement and even cure, but in advanced cases the results are slow and the treatment tedious and prolonged.

Both reports are illustrated by excellent photographs, and we must congratulate Dr. Neve on their production.

Correspondence.

"RENDER UNTO CÆSAR THAT WHICH IS CÆSAR'S."

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—Will you permit me to say a word anent the bamboo clamp in intestinal surgery which Mr. Moses speaks of on p. 194 of your April number?

It is many years ago—I cannot be precise about the date—that I read in your journal an illustrated article by Lieutenant-Colonel F. P. Connor, I.M.S., Professor of Surgery at the Calcutta Medical College, on this subject, I think, recommending the bamboo clamp as a superior instrument to the usual metal one.

I do not wish to depreciate Mr. Moses' claim to originality or resourcefulness, but the biblical heading of this short note explains my motive.—Yours, etc.,

B. J. BOUCHE,
Assistant Surgeon, I.M.D.

JUTOGH, SIMLA HILLS,
15th April, 1925.

PUBLIC HEALTH ORGANISATION.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—Anent Major Russell's letter contradicting your statement to the effect that in the appointment of District Health officers Bengal has given the lead to the whole of India, and claiming the credit for Madras, I would like to point out that the District Board of Burdwan in Bengal was the first to appoint me as their Health Officer in May 1918. I believe the District Board of Howrah appointed a Health Officer the next year and by 1921, when the Madras scheme had perhaps been sanctioned, most of—if not all—the District Boards in Bengal had been staffed with Health Officers.

Major Russell's contention for the lead to Madras therefore falls to the ground.—Yours, etc.,

J. L. DAS, D.P.H.,
Personal Assistant to the Director of Public
Health, Bihar and Orissa.

PATNA,
9th April, 1925.

A CASE FOR DIAGNOSIS.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—I thank you for publishing my letter regarding the tragic death of a *vadia*, in course of practice, in your April number.

I now write to you about another case:—A railway man aged about 42 years slept one night in his room, with coal burning in a hearth and the doors and windows closed. At about midnight he felt a desire to pass urine. He got up, opened the door and went out to relieve himself. While going he felt giddy. On returning he became senseless and fell down over the fire burning almost the whole of the right half of his body (from the axilla to the knee joint). He was admitted the next morning (at the end of November, 1924), to the Railway Hospital from where he was sent to the Muzafferpur Sadar Hospital for treatment. The wound became extremely septic but healing commenced under appropriate treatment. The case came under my treatment during the second week in February, 1925. Almost the whole ulcer had healed and I was thinking of discharging the patient when I was suddenly called to see him. He was lying senseless over his bed in a comatose condition, eyes wide open as in coma-vigil, pupils normal, pulse frequent and irregular, no fever, mouth covered with frothy mucus, and breathing stertorous. He got convulsions from head to foot every 15 or 20 minutes lasting for 2 or 3 minutes.

I immediately gave him an injection of digitalin and strychnine, repeating it after half an hour. Little improvement followed. The patient went from bad to worse and finally died in the course of two and a half hours.

When I first saw the case I had the urine examined; neither albumin nor sugar were found. The patient complained of nausea for the last five or six days and had actually vomited the previous night; he also complained of palpitation at midnight. The former I attributed to roundworms and was thinking of giving him a dose of santonin; the latter I was informed of when it was too late to do anything.

Would you or your learned readers kindly enlighten me as to what could have been the cause of the patient's death? Is death from uræmia possible so long after the accident of burning?

At the time of death he had an ulcer about the size of a rupee, which was being dressed daily with dusting powder.—Yours, etc.,

S. D. NARAIN, L.M.P.

DHAKA, CHAMPARAN,
18th April, 1925.

POST-GRADUATE WORK IN VIENNA.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—I have recently been asked by many medical men in this country for information regarding post-graduate and clinical work in Vienna; and the following information may be useful for those who think of going there, and I shall depict the conditions as I found them at the eye, ear, nose and throat clinics in the latter half of 1924.

The post-graduate work is run by the American Medical Association of Vienna, and a cordial invitation is issued to all English-speaking medical men to join the Association and make use of all the facilities to make their stay both profitable and enjoyable.

JULY, 1925.]

A knowledge of German, whilst not absolutely necessary, is strongly recommended. Practically all the courses are given in English but most profit comes to the men who can speak and write German.

Courses are divided into didactic, clinical and practical, and are arranged and listed in the Association club rooms. Fees for instruction are fixed on a standardised system and run from three to five dollars per hour for lectures or clinical demonstrations and from fifteen to fifty dollars per month for clinical work, depending upon the amount of individual teaching. The numbers for each course are limited, preference being given to those who are longest in Vienna and the fee is divided amongst the men taking the course. Hence some courses work out very cheaply, others more expensively.

The courses given in the ear, nose and throat clinics are excellent, one would not ask for anything better and the teaching is most thorough and practical. I have never seen such perfect anatomical and pathological specimens as are used for demonstration purposes in the Neumann and Hajek clinics.

The eye clinics are also good but do not reach the same high standard as the above.

For the study of refraction I would recommend men to go to Moorfield's Hospital, London, rather than Vienna. Teaching in the use of Gullstrand's Slit Lamp can also be obtained in Vienna, when it could not be got in England, but it does not come up to the standard of the wonderful annual course given by Professor Vogt at Zurich University, Switzerland.

Operation work on the cadaver is plentiful and good in the ear, throat and nose departments but more difficult to obtain in the eye department.

Operation work on the living is only obtained after a prolonged stay at the same clinic unless it can be arranged privately with some surgeon.

To get the best work one ought to remain at least six months in Vienna. Some of the courses are in great demand and it often happens that one has to wait a considerable time to get into these courses as vacancies are filled according to the length of time the applicant has been in Vienna.

Owing to the depreciation and fluctuation of the kronen, the dollar is the popular coinage and all fees are paid in it.

I have only personal knowledge of the eye, ear, nose and throat clinics but Vienna offers unique opportunities for the study of other branches of medicine, in that the large General Hospital, children's hospital, polyclinic, pathological, anatomical and hygiene institutes, where most of the instruction is given, are situated in close proximity to one another and are supplied with an immense amount of clinical material.

Pathological and genito-urinary teaching I have heard are excellent.

Weekly meetings are arranged by the Association and usually the best talent is obtained and the speakers are divided equally between English and German.

Courses start as early as 7 a.m. and go on till 9 p.m. and if one is lucky, it is marvellous how much work one can put in even in a few months.

The summer vacation begins about the 1st of July and lasts until the middle of September. By choice this is not the best time to go to Vienna but it does not interfere greatly with the courses, for nearly all the important ones are carried on by substitutes.

Many people go to Vienna with the impression that living is very cheap on account of the huge inflation of the kronen exchange. But this is a fallacy and is proved by the small number of British people one comes across except those doing medical post-graduate work, and the trend of prices is on the upward grade. Living is more expensive than in France or Italy. The hotels are expensive but one can live reasonably at pensions where prices vary from 50 dollars a month upwards and one can select these on arrival.

Outside of medicine Vienna offers many attractions, there are few other capitals in the world with environs

as charming, and in a very few minutes one can escape from the town and imbibe fresh air in the woods and fields below the spurs of the Carpathians and of the Alps along the banks of the Danube.

The opera, the public buildings and parks will occupy one's remaining spare time.

Nothing can equal the kindness shown to one by the members of the American Association in Vienna. One is made at home at once and the helping hand held out on all sides. It is only right that we in turn should reciprocate when members of the American medical profession visit this land to gain experience in whatever kind of work they are interested.

My advice to members of the profession who contemplate going to Vienna is to go and they will not be disappointed.—Yours, etc.,

E. O'G. KIRWAN, M.B., F.R.C.S.I.,
Major, I.M.S.

BERHAMPORE,
30th April, 1925.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Lieutenant-Colonel N. M. Wilson, I.M.S., made over charge of the duties of Superintendent of the District Jail at Multan to Major M. L. Puri, I.M.S., on the afternoon of the 6th May 1925.

Lieutenant-Colonel J. R. J. Tyrrell, I.M.S., an Agency Surgeon, is posted as Administrative Medical Officer in Central India and Residency Surgeon, Indore, with effect from the 7th May 1925.

Lieutenant-Colonel H. G. Stiles-Webb, I.M.S., Officiating Director of Public Health, Central Provinces, was appointed to hold charge of the current duties of Inspector-General of Civil Hospitals, Central Provinces in addition to his own, with effect from the forenoon of the 13th March 1925 to 29th March 1925 inclusive.

The services of Major H. L. Batra, M.C., I.M.S., are placed permanently at the disposal of the Government of Assam.

Major W. J. Simpson, I.M.S., an Agency Surgeon, is posted as Agency Surgeon in Bhopal, with effect from the 16th March 1925.

Bt. Major W. Ross Stewart, I.M.S., Staff Surgeon, Bangalore, is appointed, in addition to his own duties, to officiate as an Agency Surgeon and is posted as Residency Surgeon, Mysore, during the absence on leave of Lieutenant-Colonel Standage, C.I.E., I.M.S.

Major J. L. Sen, M.C., M.B., I.M.S., is appointed to act as Superintendent, X-Ray Institute, Dehra Dun, with effect from the 14th April 1925.

The services of the following officers of the Indian Medical Service are placed permanently at the disposal of the Government of the Punjab, with effect from the dates noted against their names:—

Major M. L. Puri. Dated the 30th January 1923.

Major A. M. Dick, O.B.E., M.B., F.R.C.S. Dated the 9th February 1923.

Lieutenant-Colonel V. N. Whitmore, O.B.E. Dated the 1st October 1923.

The services of Captains W. J. S. Ingram, M.C., M.B., I.M.S., and M. Murphy, M.C., I.M.S., are placed temporarily at the disposal of the Government of Burma, with effect from the date on which they assume charge of their civil duties.

Captain R. H. Malone, M.D., I.M.S., Acting Assistant Director, Bombay Bacteriological Laboratory, is appointed to act as Director of the Laboratory during the absence on leave of Lieutenant-Colonel F. P. Mackie, M.D., I.M.S., with effect from the date on which he assumes charge until further orders.

The services of the undermentioned officers of the Indian Medical Service, are placed permanently at the

disposal of the Government of Bombay, with effect from the dates noted against their names:—

Captain S. L. Bhatia, M.C., M.D. Dated the 4th September 1923.

Major P. K. Gilroy, M.C., M.D., F.R.C.S. Dated the 14th November 1924.

LEAVE.

In modification of the orders already issued, Colonel H. Ainsworth, M.B., F.R.C.S., I.M.S., Inspector-General of Civil Hospitals, Bihar and Orissa, is granted leave on average pay for 6 months and 1 day and leave on half average pay for the remaining period up to a maximum of 8 months leave in all, with effect from the 13th March 1925, the date on which he availed himself of the leave.

Lieutenant-Colonel W. R. Battye, D.S.O., I.M.S., an Agency Surgeon, is granted leave on average pay for 6 months, under Fundamental Rules, with effect from the 7th May 1925.

Lieutenant-Colonel C. B. McConaghy, I.M.S., an Agency Surgeon, is granted leave on average pay for 8 months, under Fundamental Rules, with effect from the 14th March 1925.

Lieutenant-Colonel R. F. Standage, C.I.E., I.M.S., an Agency Surgeon, is granted leave on average salary for 1 month, with effect from the 1st April 1925, or the date on which he avails himself of it.

The previous orders granting leave for 1 year to Captain R. H. Malone, M.D., I.M.S., Acting Assistant Director, Bombay Bacteriological Laboratory, are cancelled.

PROMOTION.

Lieutenant to be Captain.

C. R. Henderson, M.B. Dated 29th March 1925.

MISCELLANEOUS.

With reference to Army Department Notification No. 2649, dated the 15th August 1919, the Governor-General in Council is pleased to direct the publication of the following Royal Warrant, dated the 17th March 1925, regarding the age for compulsory retirement of an Indian Medical Service officer holding the appointment of Director, Medical Services in India:—

George R. I.

Royal Warrant.

Whereas we deem it expedient in the interests of the Service to make the following change as to the age at which officers of Our Indian Medical Service holding administrative appointments shall be placed on the Retired List.

Our Will and Pleasure is that an officer of Our Indian Medical Service holding the appointment of Director of Medical Services in India shall be placed on the Retired List on attaining the age of 60.

Our Warrant dated 13th June 1919, shall be amended accordingly.

Given at Our Court, at St. James's this 17th day of March 1925, in the fifteenth year of Our Reign.

By His Majesty's Command.

(Sd.) BIRKENHEAD.

NOTES.

THE NORDHOFF-JUNG CANCER PRIZE.

We are requested by the Biological Department of Georgetown University, W. Washington, D.C., U. S. A., to publish the following notice:—

"The Commission for the distribution of the Prize for Cancer study founded by Dr. Sofie A. Nordhoff-Jung, in agreement with the Foundress, has resolved to distribute the Prize from now on only every two years to the double amount of the sum allotted heretofore, that is one thousand (\$1,000) Dollars. The next prize will reach distribution in 1926."

MESSRS. WATSON & SONS' X-RAY CATALOGUE.

MESSRS. WATSON & SONS (ELECTRO-MEDICAL), LTD., Sunic House, 43, Parker Street, Kingsway, London, W. C. 2, have recently published Parts I. and II. of a new general catalogue which will be of considerable interest to radiologists and hospital superintendents generally. By the adoption of a comprehensive sectional system with a liberal allowance of both sectional and general indices, reinforced by a novel system of item enumeration in which the first three figures of the item number form the page reference, the catalogue has been made especially easy for reference. Thus in the scheme for a complete installation for all purposes, the numbers given at the side of each apparatus mentioned enable one immediately to turn up the pages where detailed descriptions of each is given. The whole volume is admirably got up, very informative with regard to radiology in general, and free from trade puffs and superlatives.

Among many other interesting items listed are a new hospital transformer outfit for generating x-rays, devised to secure numerous economies in detail of working, but still efficient and suitable for all but the heaviest demands, and adaptable for either direct or alternating current; a new dental x-ray apparatus, where the tube and the high tension transformer are both immersed in oil in an earthen container, forming a self-contained unit, with all external high tension leads eliminated, thus doing away with the need for extreme caution in using x-ray apparatus for dental work; a portable x-ray outfit, consisting of four packages, each light enough to be carried by hand, if used for an alternating current not exceeding 125 volts; or of six such packages for direct current, and reaching the high figure of 90,000 peak volts, yet suitable for connecting with the ordinary domestic electric supply; and a constant tension x-ray outfit for deep therapy. The section on radium therapy is of general interest, as an account is given of the metal itself, of types of containers, applicators and accessories. At the end of the catalogue is a very useful bibliography of recent works on x-ray and radium work in general.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "The Indian Medical Gazette," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to the *Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of the *Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

THE TREATMENT OF FRACTURES OF THE ELBOW JOINT.

By H. HALLILAY,

LIEUT.-COLONEL, I.M.S.,

A BROKEN bone is an immediate calamity to the sufferer, entailing weeks or even months of pain, disability and financial loss, with the possibility of ending in a lifelong disaster.

The apathy of surgeons in general to this class of injury, and the resignation of the public to deformity and disability which so often follow it both spring from the same cause; the knowledge that the results are too often mediocre at best and very bad indeed at the worst.

A cynical piece of advice current in my student days and attributed to a famous Barts surgeon was:—"If a patient ever comes to you with a Colles' fracture, give him five shillings and tell him to go to the doctor at the other end of the street."

Whether the advice be sound or unsound, it illustrates the fact that fractures do not or did not arouse that interest amongst surgeons that is extended to more dramatic and picturesque emergencies although the matter is of the greatest moment to the patient.

When I was House Surgeon in my London Hospital, it was rare indeed for the visiting surgeon to put up a fracture himself; that business devolved almost as a matter of course upon the Resident.

This was not because the surgeon lacked humanity or conscience, but was merely a tacit confession that the difference between the results obtained by himself and those of the veriest tyro was so slight as to be for all practical purposes negligible.

When the surgeon is confronted with one of these somewhat formidable cases which give the title to this article, he has a choice of two lines of action. He can put the fracture up in full flexion in the hope that in some mysterious way the fragments will be beguiled into their own places so that the bone will be restored to its original shape, or he can do an open operation and replace the pieces very much in the manner of one solving a jigsaw puzzle, insuring against any subsequent displacement by fixing the fragments by means of Lane's plates and screws or by wiring or any other means of internal fixation which may appear suitable.

The first method has the sanction of no less an authority than Sir Robert Jones, the second is advocated by a great original surgical genius—Sir Arbuthnot Lane.

It is claimed by the followers of the first method that it is possible to replace the fragments in their own places and that once replaced the tendon of

the triceps will prevent displacement while the closure of the joint in full flexion will prevent the deposition of cellus in situations which might lead to the limitation of movement afterwards.

Those who practise this method express their complete satisfaction with the results which they obtain and say that their results are so good that they never wish to try any other. Were the enthusiasm of the patient for the method as great as that of the surgeon, one would probably be convinced of its excellence and there would be little to do except to register one's approval, but, as a matter of fact, the end results of many of these

No. I.

Photo taken on 20-2-24.

cases treated in this manner are highly unsatisfactory to the patient. Too often there are limitations of movement, usually in the direction of extension and even more frequently a deviation in alignment of the forearm on the humerus.

The result of this latter deformity is to impose a serious handicap in the playing of games, a formidable disadvantage in a country where proficiency in athletics is accounted more than the wisdom of Solomon.

What commonly occurs is that a child of 9 or 10 years of age sustains a T-shaped fracture of the humerus which is treated by immobilization in full flexion. After a longer or shorter interval

the limb regains a measure of its former mobility, the child does not complain and the medical attendant assures the parents that the result leaves nothing to be desired. Only when the child attains school-going years and comes under the notice of the games master does the deformity attract attention and too late it is discovered that the child has acquired a lifelong disability as a result of the treatment to which the fracture has been subjected.

Surgeons speak of these cases as rare, or only occurring in the practice of those less skilful than themselves in the treatment of this class of injury.

In my own practice in the course of the past few years, I have frequently been asked to advise

No. II.

Photo taken on 21-2-1924.

as to the best treatment of these disabilities; I infer, therefore, that these unsatisfactory results are not so uncommon as is generally supposed; in any case the surgeon who originally treated the limb would be the last to be consulted for the deformity for which rightly or wrongly he is held responsible.

To anyone who has any experience in the operative treatment of these injuries it is very difficult to understand how the surgeon can expect to replace the fragments by manipulation through a pad of thickened and oedematous tissue if the displacement is of more than the slightest degree, in view of the difficulty of restoring the

contours of the bone even with the facilities afforded by an open operation.

The radiograms published with this article illustrate the difficulty of dealing with these fractures by external manipulation alone, however competent the surgeon in this method of treatment.

I should explain that in the case in question this result was obtained after two previous attempts at "setting," of course under full anaesthesia, so the unhappy patient was subjected to three separate manipulative offensives under chloroform before the attainment of the very mediocre result illustrated by the skiagrams.

The boy's parents were then told that the results left nothing to be desired and that in a very short time it would be impossible to tell that a fracture had taken place.

As many months after the injury the boy was unable to extend his arm beyond a right-angle, it will, I think, be admitted that the standard accepted by many members of our profession with regard to the end results of treatment of these injuries is not an exacting one.

The following is a brief history of the case:—A. B., aged 13, fractured his arm by falling from a height. In February 1924 the arm was "set" under an anaesthetic on the same day of the accident.

The next day the arm was reset under chloroform and the following day as the fragments were still in a bad position one more attempt was made to replace them under an anaesthetic.

The final result of these three manipulations is shown in skiagram No. 3.

A critical examination of these skiagrams will well repay the trouble. Skiagram No. 1 shows the fracture after the first "setting"; No. 2 shows the results of the second "setting"; No. 3 shows the results of the third "setting"; No. 4 was taken 24 days after the last occasion on which the arm was "put up," and finally, No. 5 was taken nearly two months after the original fracture. This skiagram is rather misleading as it would appear that the arm is fully extended, whereas the patient was and is unable to extend it beyond a right-angle. It displays admirably the lateral deviation to which I have adverted in the earlier part of the article, both bones with the attached articular surfaces of condyles being displaced to the ulnar aspect of the limb with a resulting bayonet-shaped deformity and distortion of the outline of the limb.

If the skiagram No. 1 be examined carefully it will be seen that the articular condyles of the lower extremity of the humerus preserve their normal relationship to the corresponding surfaces of the head of the radius and of the olecranon respectively.

What usually happens in these fractures is that the break runs through the coronoid and olecranon fossae and a variable distance above the external and internal epicondyles, a continuation of the original violence carrying the forearm with

No. IV.

Photo taken on 15-3-1924, i.e., 24 days after arm was "put up" in No. 3.

the attached lower end of the humerus bodily backward and upward behind the lower end of the upper fragment.

The fact that the articular surfaces of the lower end of the humerus maintain their normal relationship to the bones of the forearm is explained when it is remembered how these bones are tethered together by the ligaments of the joint and by the origins of the flexor group of

No. V.

Antero posterior taken on 26-4-1924.

muscles on the internal aspect of the joint and that of the origins of the anconeus and the extensor muscles on the external aspect.

I have drawn attention to these anatomical details as they have a very important bearing on the results of the treatment by supination and full flexion.

As the forearm is flexed on the upper arm the lower fragment of the humerus is rotated with it by the drag of the stretched extensors and anconeus so that by the time that the arm is in a position of full flexion the lower fragment rotates with it 90° or more.

In other words the lower fragment is rotated on the upper through 90°, and if union takes

place that arm can never attain more than 90° of extension, or in ordinary language the patient will never be able to extend his arm beyond a right-angle.

A glance at the skiagram will show that this is what has taken place in the case under discussion, and explains the inability of the patient to extend his arm beyond a right-angle.

Skiagram No. 3 shows very clearly the rotation which has taken place of the condyles of the humerus in harmony with the flexion of the forearm.

Skiagrams No. 4 and 5 show the shaft of new bone which is being laid down laterally in consequence of the faulty alignment of the fragments, the whole forearm being displaced inwards on the upper fragment.

In time the original shaft in its lower two-thirds will be entirely absorbed and will be replaced by the new shaft now shown in process of building. Note too the mass of callus which has been laid down behind the lower end of the upper fragment completely locking this part of the joint. This state of affairs hardly bears out the contention of those who practise this method of treatment that the strap of the triceps by its pressure prevents the deposition of callus at the back of the joint!

As a rule the worse the fracture the greater the indication for open operation, even the most enthusiastic advocate of manipulative methods can hardly claim that he is better able to deal with these badly comminuted fractures through a pad of œdematous and swollen tissues than would be the case were the parts clearly exposed to the eyes and instruments of the surgeon.

I hope to deal with the operative treatment of these difficult cases in a subsequent paper.

A PRELIMINARY NOTE ON THE PHARMACOLOGY AND THERAPEUTICS OF *ADHATODA VASICA* (BASAK).

By R. N. CHOPRA, M.A., M.D. (Cantab),

MAJOR, I.M.S.,

Professor of Pharmacology,

and

SUDHAMOY GHOSH, D.Sc., F.R.S. (Edin.),

Professor of Chemistry,

School of Tropical Medicine, Calcutta.

(Indigenous Drug Series No. 6).

Adhatoda vasica is a small evergreen sub-herbaceous bush belonging to the natural order acanthaceæ. It grows all over the plains of India and in the lower Himalayan ranges ascending to a height of about 4,000 feet above the sea-level. In Sanskrit it is called *Arusak* (not angry), *Vansa* (giving perfume), *Vrisa* (chief), *Sinha Mukhi* (lion mouthed). In Hindi it is called *Arusha*, in Bengali *Bakas* or *Vasaka*, in Northern India it is known by the name of *Bhekkar* or *Basuti* and in Persian it is called *Bansa*. The name *Adhatoda* is of Tamil origin.

The plant has minutely pubescent entire leaves arising from swollen nodes; the flowers are white or purple in colour. It is well known to the people throughout the country and a yellow dye is commonly obtained from its leaves. The leaves, the root and the flowers are extensively used in indigenous medicine as a remedy for colds, cough, bronchitis and asthma. It is often given in the form of juice extracted from the leaves, mixed up with ginger or honey, in doses of $\frac{1}{2}$ to 1 ounce. A decoction is also made from the leaves, and dried leaves are administered in powder form in doses of 30 grains. Both the decoction and powder form constituents of many preparations used in the Ayurvedic medicine for various affections of the respiratory tract. In chronic bronchitis and asthma it is said to be specially efficacious. For the latter disease the dried leaves are made into cigarettes and are smoked. U. C. Dutta says "the medicine was considered so serviceable in phthisis that it was said no man suffering from this disease need despair as long as *Vasaka* plant exists." Juice of the leaves is used in diarrhoea and dysentery and in Southern India the powdered leaves are used in malarial fevers. In Burma and in Northern India the leaves are applied locally in form of poultice on rheumatic joints, inflammatory swellings and in neuralgias. The leaves are said to be toxic to all forms of lower life, prevent the growth of lower aquatics and check the development of parasitic vegetation. According to Watts, the alcoholic extract of the leaves is poisonous to flies, fleas, mosquitoes, centipedes and other insects. From the above remarks it will be seen that the plant is popularly believed to have remarkable medicinal properties. We, therefore, decided to investigate the claims made regarding its efficacy.

CHEMICAL COMPOSITION.

As long ago as 1888, Hooper published details of chemical analysis of the drug carried out by himself. He found that an odorous volatile principle probably of the nature of an essential oil and a non-volatile body of the nature of an alkaloid called 'vasicine' were present. Hooper's work was confirmed by Boorsma of Java, who further investigated the alkaloid and tested its physiological properties but we have not been able to find any records of this work. We have made a thorough analysis of the drug and worked out its pharmacological action and therapeutic effects. The details of this work will be published in the *Indian Journal of Medical Research* and we will confine ourselves here to a brief summary of the results attained. Owing to want of suitable apparatus we could not collect a sufficient quantity of the essential oil to test its physical, chemical and physiological properties but this difficulty has been removed and the work is in hand.

The alkaloid is found in the leaves to the extent of 0.25 per cent. The base occurs as

needle-shaped crystals and has a melting point of 182°C . It is easily soluble in alcohol, is slightly soluble in cold water but more so in hot water. A 2.0 per cent. solution in chloroform is optically inactive. Vasicine hydrochloride occurs in light cream-coloured crystals and has a melting point of 180°C .; it is very soluble in water. Vasicine tartarate is also prepared and is a soluble salt. The molecular weight of vasicine was determined and found to be 188 which agrees with the empirical formula of $\text{C}_{11}\text{H}_{12}\text{N}_2\text{O}$ found by analysis.

PHARMACOLOGY OF VASICINE.

The alkaloid vasicine and its salts are not very toxic to undifferentiated protoplasm. It has little or no effect on the free living protozoa such as *Paramœcium caudatum* nor has it any toxic or inhibitory effect on the cultures and growth of streptococci, staphylococci, *B. coli*, *B. diphtheriæ* or *B. tuberculosis*. It is possible that the antiseptic properties of the leaves recorded by previous observers may be due to the volatile principle. Solutions of concentrations of 1 to 5 per cent. are not irritant to the mucous membrane. The alkaloid has a bitter taste but has no marked effect on the movements of the alimentary canal. In high concentrations (1 in 20,000) the peristaltic movements of the isolated gut are inhibited, probably owing to depression of the vagal endings. Intravenous injections in animals produce a slight fall of blood pressure due partly to direct depressing effect on the cardiac muscle and partly to depression of the terminations of the vagi in the heart. There is no effect on the blood vessels.

In lungs of experimental animals the alkaloid, when given intravenously, produces a slight but a persistent broncho-dilation. This action is in all probability due to depression of the vagal terminals in the bronchi as it is absent after small doses of pilocarpine. After administration of atropine the broncho-dilator effect is very much pronounced. The drug has a well marked expectorant action and it is probable that the essential oil plays an important part in this direction.

THERAPEUTIC USES OF *Adhatoda Vasica*.

We have tried clinically an alcoholic extract made from fresh and dry *adhatoda* leaves during the last three years. Previously a tincture made from the leaves was given an extensive trial in various civil hospitals and dispensaries in different parts of India at the instance of the Indigenous Drugs' Committee. Most of the evidence produced showed, and our own conclusions are in accord with it, that the drug has a well marked expectorant action. In acute bronchitis we found that it always afforded relief, specially where the sputum is thick and tenacious, acting in very much the same way as ipecacuanha. In chronic bronchitis the cough is relieved, the sputum is liquefied so that it is brought up more easily.

The depression of the vagal terminations further relieves irritation and spasm of the bronchioles. We have also tried the extract in a number of cases of bronchial asthma but relief given by it was not very marked. As our animal experiments have shown the synergistic action of atropine and vasicine we are now trying a combination of the extract with belladonna preparations in cases of vagotonic origin and the results will be published in due course.

As regards the effect of the drug in tuberculosis of the lungs our conclusions are also in accord with those of the Indigenous Drugs' Committee. The drug is absolutely useless in curing or preventing the progress of this disease in experimental animals or human beings. There is no doubt, however, that it relieves the irritable cough by its soothing action on the nerves and by liquefying the sputum which makes expectoration easier.

CONCLUSIONS.

(1) Chemical analysis of *Adhatoda vasica* shows the presence of two active principles:—

(a) An alkaloid vasicine whose empirical formula we have found to be $\text{C}_{11}\text{H}_{12}\text{N}_2\text{O}$ = molecular weight 188.

(b) Traces of a volatile principle of the nature of an essential oil.

(2) Vasicine has no marked action on the alimentary canal or on the circulation. It produces slight but persistent broncho-dilation in experimental animals and this effect is considerably increased after administration of atropine.

(3) Clinically a fluid extract prepared from the leaves has well marked expectorant properties and relieves bronchial spasm. It has no effect whatever in pulmonary tuberculosis.

MERCUROCHROME 220 IN THE TREATMENT OF MALARIA.

By A. NEAVE KINGSBURY, M.B., B.S., D.P.H.,
D.T.M. & H.,
and

K. KANAGARAYER, I.M.S. (Singapore),
From the Institute for Medical Research, Kuala Lumpur,
Federated Malay States.

SINCE the introduction of mercurochrome 220 as a urinary antiseptic, it has been propelled by its enthusiasts along the path which is traversed by many of the new drugs, until it would seem that a veritable panacea is now available for suffering humanity.

Malaria has been included in the inventory of diseases which are amenable to treatment by this dye, which is a fluorescent compound of mercury—the di-sodium salt of 2,7-dibromo-4-hydroxymercurifluorescein—and reports of the

action of mercury and of fluorescent substances in the treatment of malaria would indicate that it should not be without action as a plasmodicide.

Thus Barlow (1916) has described beneficial results from the exhibition of mercuric chloride in malaria. Greig and Ritchie (1917) showed that a combination of mercuric chloride and quinine was more effective than quinine alone in reducing the size of malarial spleens, though they were less sanguine than Barlow of the therapeutic value of mercury. Cremonese (1918) claimed that mercury is a powerful curative agent for malaria. Attempts have been made to increase the effect of quinine on the parasites by the injection of fluorescent substances such as fluorescein or eosin and Rusznyak (1920) found that such substances increased the value of quinine both in vitro and in vivo.

In view of the possibilities of mercurochrome we decided to test its value as a curative agent in malaria and thanks to the courtesy of Dr. E. A. O. Travers, we were enabled to select a benign tertian and a malignant tertian case. The drug was made up to a strength of 0.5 per cent. and a daily intravenous dose of 20 c.c. was given.

Case I.—Double benign tertian infection. The patient was a Tamil, 20 years of age, and weighed 95 lbs. He had had an attack of malaria three months previously and his spleen was enlarged to the costal margin. The temperature on admission to hospital (March 2nd) was 103.1°F.; he was given a purgative and aspirin grs. x. The following morning a double benign tertian infection was diagnosed from blood films, and mercurochrome was administered on the 3rd, 4th and 5th of March. Aspirin was also exhibited to control the temperature. On the 6th of March mercurochrome was discontinued as a stomatitis developed which required energetic treatment. The following day aspirin was withdrawn and quinine grs. xxx daily prescribed, but the patient refused to swallow it. On the 8th of March the temperature rose to 102.9°F., there was a rigor, after which the patient took the quinine, and the temperature rapidly fell to normal. On the 16th of March he was discharged at his own request.

Daily blood examinations were carried out on the patient and the percentage of infected corpuscles showed little, if any, diminution from the 3rd until the 9th of March. The *P. vivax* cycle continued in a normal manner and the mercurochrome had no influence on the staining properties of the parasites. The exhibition of quinine was followed by a speedy disappearance of the parasites. From the blood examinations we concluded that the partial control of the temperature was due to the aspirin rather than to the mercurochrome.

Case II.—Malignant tertian infection. This case was of Chinese (Hokian) nationality, who had had occasional attacks of fever since his arrival in Malaya 15 years before, but his spleen was not enlarged. His age was 45 years and he weighed 140 lbs. He was also admitted to

hospital on the 2nd of March and his temperature was then 99.4°F. He was given a purgative and the following morning malignant tertian rings were found. On the 3rd, 4th and 5th of March intravenous mercurochrome was given

Chart I.

Case I.—Double benign tertian infection treated with mercurochrome.

Chart II.

Case 2.—Malignant tertian infection treated with mercurochrome.

and on the 6th of March injections were discontinued on account of stomatitis. The temperature was normal on the 5th and 6th, but rose again on the 7th. Quinine grs. xxx was then exhibited daily until the 17th, when he asked for his discharge.

Blood examinations showed the presence of parasites until the day following the prescription of quinine though the percentage of infected cells in the peripheral blood fell somewhat from the 3rd to the 6th.

This patient was given no aspirin, but it is doubtful if the fall in temperature can be ascribed to the mercurochrome. We have seen a number of malignant tertian cases which after admission to hospital lose their fever and parasites decrease, sometimes even disappear from the peripheral blood, even if specific treatment is withheld. This we regard as evidence of partial immunity which, aided by rest in bed and good feeding, is able to deal with the infection sufficiently to cause such a reduction in the number of parasites that all symptoms are lost.

CONCLUSIONS.

In the above case of benign tertian malaria, a total of 0.3 grammes of mercurochrome was given over three days. On the withdrawal of aspirin and three days after the last mercurochrome injection a typical rigor occurred with a temperature of 102.9°F. The malignant tertian case received a similar quantity of mercurochrome and fever recurred two days after the last injection. The dye appeared to have little effect on the number of malaria parasites in the peripheral blood and caused no modification in their staining properties.

In neither case did albuminuria develop.

We consider that the action of mercurochrome on malaria parasites is practically negligible, and that, in view of the unpleasant sequelæ which result from its exhibition, it should not be given in cases of malarial fevers.

CATARACT EXTRACTION.

Notes on 17,000 Operations.

By JAMES M. MACPHAIL, M.D. (Glas.),
Bamdah Mission Hospital, Monghyr District.

BANDAH is a Santal village in the district of Monghyr in the Province of Bihar. The Mission Hospital is one of three that are maintained by the Santal Mission of the United Free Church of Scotland Santal Mission. As the work of this Mission lies mainly among the Santals, an aboriginal tribe living in small villages in the more remote parts of the country, the stations are located, not in populous centres, but in the "jungle". Bamdah with a population of about four hundred people is larger than most of the villages in the neighbourhood, but it is about the average size of the Indian village. It must

not be supposed that cataract is a very common disease in this part of the country. Of the 17,000 operations to which these notes refer, only two were performed on people living in Bamdah. Blind people and other eye cases travel very long distances to hospital, often begging their way, and the railway authorities often give them free passes. (There is a railway station, Simultala, on the East Indian Railway, about fifteen miles from Bamdah.) The fact that the hospital is situated on a popular pilgrim route by which every year hundreds of thousands of Hindus travel from North India to Baidyanath, twenty miles from Bamdah, and thence to Jagannath or Puri, has no doubt helped to make it known and made patients disposed to come to it. It is a very common occurrence for a patient to come to the Christian hospital to have his sight restored and then to travel on to a Hindu shrine to offer thanksgiving. The total here recorded is the accumulation of thirty-four years' work, and has been of slow growth. Beginning work in 1890, I carried on for four years without a hospital, operating on my writing table and finding accommodation for the patients in odd corners. For nine years longer the verandah of the hospital served as an operating room, but a proper operation room was built in 1903. In the first year, after the opening of the hospital, the number of cataract operations was 34. The numbers increased till they reached 1,440 in 1921, and that average was maintained for the two following years, 1924 promised to be the record year; 900 cataracts were extracted in the first two months, but I left for furlough in March. It may be noted here that there are seasons for cataract operations (and for other operations for chronic conditions not demanding immediate relief) in India. At least 90 per cent. of the people are cultivators of the soil and they choose a time for operation when there is not much work to be done in the fields. The favourite season, in North India at least, is the interval between the harvest and the sowing, from January to June. Then parties of patients often come from one village or locality, personally conducted by a former patient, who shows his gratitude by bringing more grist to the mill and claims a share in the religious merit which is supposed to be the supreme object of our work. Thus it happens that in the busy season as many as fifty or more operations may have to be performed in a day. It should be explained that the hospital is a general one; although the great majority of the operations are on the eye a fair amount of general surgery and a large medical practice have also to be undertaken. In 1923 the total number of operations was 3,400, of which 2,890 were eye operations. Of these 1,426 were for cataract. Next to the cataracts the most numerous operations were 526 iridectomies (for corneal opacities and glaucoma); 382 expressions for trachoma; 194 entropions; and 149 tattooings for leucomata. (When both eyes were operated on, that was

recorded as two operations. One operation might have to be recorded as a failure, the other as successful.) My wife, who is a medical graduate, has performed a large number of the general operations and a few cataracts also. During the very busy spell at the end of 1923 and the beginning of 1924, I had the efficient help of Dr. Arthur F. Smith, who came to relieve me for furlough. On previous furloughs the work was carried on by Dr. James Kitchen and Dr. J. N. Turnbull. In 1924 the number of cataract operations was 1,519.

The preparation of the patient does not, as a rule, begin till he or she is on the operation table. We have no "waiting list"; owing to the crowds of patients and the limited accommodation, we try to dispose of the cases with as little delay as possible. Work in India is not without its compensations; we have abundance of fresh air and sunshine, and are less troubled with sepsis than one would expect. A visitor to the hospital, who had been trained as a nurse in the Edinburgh Royal Infirmary, once astonished me by remarking:—"How clean the people are here, compared with Edinburgh." The difference was that the people in Bamdah Hospital wore very few clothes and that, on account of the heat of the climate, they bathed, as a rule, every day. We have often fairly cold weather with a touch of frost at times in January. At such times many of the people give up bathing and are much dirtier. The procedure for disinfecting the eye is to clean the skin thoroughly with petrol (we used benzine for a time but petrol is much cheaper and seems to do as well), then with soap and water, and finally, with corrosive sublimate, 1 in 2,000. The speculum (all the instruments are boiled, except the knives, which are dipped in pure carbolic and then washed in boiled water, and kept between operations either in rectified spirit or in lysol solution, 1 in 20) having been introduced the conjunctival sac is syringed out with corrosive sublimate, 1 in 4,000. In the early days cocaine was the anæsthetic used. Eucaine was then used instead as it was much cheaper, but as it was found to have a vasodilator action it was combined with adrenalin when that drug was introduced, a 2 per cent. solution of cocaine hydrochloride being mixed with an equal amount of adrenalin chloride, 1 in 1,000. When the war broke out, it was impossible to obtain eucaine, but owing to the large quantities of contraband cocaine that had been seized by the Government of India that drug was still available and we took to using it again and have continued to use it. The method that has been adopted during the last two or three years has been to use the salt itself in solid form. This has been found to be more economical, and the powder seems to be less irritating than the solution. About half a grain is applied to the conjunctival sac. Whether the solution or the powder is used, the first application is made about twenty minutes before the operation, the second, when the patient lies

down on the table. If eucaine is used, it cannot be applied as a powder, for it does not dissolve in the tear water as cocaine does. For many years now capsules of nitrite of amyl have been kept in readiness for cases that might show signs of collapse as the effect of the cocaine, but we have never had occasion to use them. Chloroform is given to children, but hardly ever to adults. The retching and sickness that often follow the administration of chloroform are a nasty complication in cataract extraction. If deeper anæsthesia than ordinary is necessary, as in cases with high tension, the cocaine may be given more freely, combined with adrenalin, which seems to reinforce its effect. (We do not combine adrenalin with cocaine as a routine, as we do with eucaine, as the cocaine has less effect as a vasodilator.) But the best thing to do in an eye with abnormal tension is to perform a preliminary iridectomy, postponing the extraction of the lens.

In the operation itself the only serious departure from the usual procedure is the rupturing of the capsule, not with the cystitome, but with the point of the cataract knife while the corneal incision is being made. I can claim no originality for this modification, as I saw it being practised by Pope in Madras in 1902, and he told me he had adopted it from his predecessor, Drake Brockman. It has several advantages. One very important advantage is that it saves an instrument. Undoubtedly the most serious risk to which the cataract patient is exposed is that of septic infection at the time of operation, and the fewer the instruments used the better. Another advantage is that it saves time, and the sooner the operation is finished and the eye bandaged, the better is the prospect of rapid and satisfactory healing. Then on rupturing the capsule, we find out the character of the cataract. If there is a flow of milky matter, we know we have a small nucleus to deal with and a smaller corneal incision is necessary. Again, if the capsule is tough, resisting the point of the knife, we know we have a case in which the removal of the lens in the capsule may be attempted with a fair measure of safety. One instrument which I invariably use and prize highly but which, I do not think, is in general use is Pagenstecher's lens expressor, made of porcelain. The curve fits that of the cornea and it exercises more even pressure than any other instrument I have seen, and being of porcelain it is less likely to injure the cornea than a metal instrument. It is thus very useful for stroking the cornea after the expulsion of the lens, to remove the debris. In my opinion it makes irrigation unnecessary. It also has to some extent the effect of an iris retractor.

For dressing, pledgets of absorbent cotton wool that have been steeped for several hours in a 1 in 2,000 corrosive sublimate solution are used, and they are kept in position by a roller bandage made of the light cotton cloth called *bafta* that is

sold in the Indian bazars. As a rule, both eyes are bandaged. Nearly all our patients are accompanied by relatives who cook for them and attend to them generally; if a patient has no one with him and has sight in the eye that has not been operated on, that eye is left unbandaged. If all is well the eyes remain bandaged for two days, the dressing being done every second day. (In India we learn to be explicit about these things, for, if a patient is told that he will be dressed the second day, he understands that to mean the next day.) On the eighth day the bandages are removed and the patient is kept two or three days longer in hospital before being allowed to go home. It should have been mentioned that after operation a few drops of a 1 per cent. solution of acriflavine are instilled into the conjunctival sac. At subsequent dressings a 1 in 4,000 corrosive sublimate solution is used to clean the eyelids, but atropine is not used unless there are signs of iritis. Every patient takes home with him a good supply of corrosive sublimate, 1 in 5,000, and is told to use it as an eye lotion morning and evening for ten days or longer, if necessary. Most of the patients are vegetarians, for which they are none the worse, from the surgical point of view, and diet is a simple matter. The Indian patient attaches very great importance to diet in the treatment of disease and insists upon being told what he should eat and what he should avoid while under treatment. He divides all articles of food into two kinds:—*pahlan*, the eating of which promotes recovery, and *baran*, the things that retard it. The advice, we give them, is to confine themselves to soft foods, boiled rice and pulse, and to avoid food that requires chewing. It sometimes happens that there is a patient who has no one along with him and who on account of caste scruples is unable to take food cooked by any one in hospital or near it. In such cases a kind of peas-meal that is in common use is very useful. It is made by roasting peas and then grinding them and all that is necessary is to mix it with water. The rice water in which the more well-to-do patients have boiled their rice is usually available to eke out the scanty food supplies of the poor. (The patients bring their own food, or get it from other patients.)

It has been mentioned that a preliminary iridectomy is considered to be the best plan to adopt in cases of high tension. It may be added that a preliminary iridectomy is an advantage in any case. We have not reverted to making this the rule, the delay involved would be hardly justifiable in ripe healthy cataracts; but every patient who consults us about immature cataracts and every patient who has come to have a ripe cataract removed and whose other eye has an unripe cataract is strongly advised to have a preliminary iridectomy. Cataract extraction where there has been a preliminary iridectomy is a very simple and safe operation, especially when the capsule is ruptured with the point of the cataract

knife, for then the knife is the only instrument that enters the eye-ball.

The operation of removing the lens in the capsule, as advocated and practised by Colonel Henry Smith, is very popular in North India, and there is a great deal to be said in its favour. When Smith first began to practise it, I gave this method what I considered a fair trial by doing a hundred extractions as far as possible according to his directions. I gave it up because it seemed to me to be too risky, the cases of escape of vitreous being too frequent. It should be added that at first Smith extracted without an iridectomy and I followed him in this respect, but afterwards he did the operation with iridectomy. Smith also said that he would not advise anyone to operate by his method unless he had received personal tuition from him, and I have not had that advantage. He also insists upon the necessity of having a specially trained assistant, and that is another difficulty in the way of the general adoption of the operation. When successful, it is a beautiful operation, and as I have indicated above, I do it occasionally in cases where the capsule is tougher than usual. The case for which Smith's operation is specially indicated is the immature cataract, and it seems to be more easily performed and safer in such a case. As Smith truly says, many a man is ruined, while waiting for his cataracts to ripen. An old *rani* with unripe cataract consulted me a few months ago. She was still able to sign her name but she could no longer read the cheques she was asked to sign and she feared that her estate was being swindled away from her. She was not willing, however, to have an operation, as she had been told that there was a medicine that cured cataract if dropped into the eye; but if I had had more experience of Smith's operation I would probably have pressed her to submit to it.

The rule in selecting cases for operation is:—If the patient can no longer count fingers but can still distinguish light from darkness and has a pupil that responds to light, he is ready for operation. Of course, cases of absolute blindness are rejected, but there are cases, where there is still some perception of light but where the iris is inactive, that are not to be operated on without careful consideration. As a rule, it is better to do a preliminary iridectomy. For the last year or two we have been testing practically all cases with the tonometer, but I attach as much importance to the action of the pupil as to the reading of the tonometer. In one case, for example, I was at first unwilling to operate in a case of cataract where the pupil did not respond to light, but on the tonometer being applied the reading was moderate and re-assuring, with the result that I operated and the eye was lost from hemorrhage.

On one point I have never had any doubt and that is the advisability of the iridectomy. Experience has amply confirmed the advice received from Maitland Ramsay in student days, that

without iridectomy you will get some prettier results, but that with iridectomy you will have a larger proportion of successful cases. But in the cases where the patient expels the lens before an iridectomy has been done, it is better not to attempt to do an iridectomy, and the iridectomy may be omitted in cases of soft cataract which drain away when the capsule is opened.

We see a great many cases of cataract which have been couched. In too many cases they come to us because they are hopelessly blind. One eye was operated on by a *rawal*—(as the professional coucher is called)—and at first the results seemed good but the dislocated lens, acting like a foreign body, set up irritation and the sight of both eyes was completely lost from iridocyclitis. In a good many cases I have been able to fish out a dislocated lens by means of Taylor's vectis before the eye had become blind. The coucher, however, scores an occasional success—indeed, I have had the humiliation, in one case at least, of operating unsuccessfully on a patient whose other eye had been successfully operated on by couching. It is hardly conceivable that the *rawals* could maintain their reputations if they were not sometimes successful. In one kind of cataract, the morgagnian, with a small nucleus and a milky cortex their results are often good. In endeavouring to dislocate the lens the coucher very likely ruptures the capsule, the milky matter escapes and is absorbed and the small nucleus lies quiescent in the posterior chamber.

Owing to the prevalence of corneal ulceration, due in a great many cases to small-pox, there is a large number of cases of cataract complicated with corneal opacity. It is a very common occurrence to do an iridectomy for corneal opacity and then to find behind it a cataract. In many cases the cataract is really traumatic, due to the ulcer having perforated and being of soft consistency it can be evacuated through the opening made for the iridectomy. Trachoma is a very common complication and in many cases demands prolonged treatment before an operation for cataract can be performed with safety. Dacrocystitis, however, is less common than at home; in 1923 I performed only 7 operations for extirpation of the sac.

For testing results, as in other respects, our methods are rough and ready. Probably not more than 5 per cent. of the patients can read or write. As a rule, if the patient can see to sow and reap and to herd cattle, he is content. A case is recorded as successful if fingers can be counted in the case of an illiterate person, or if good large print can be read with the help of glasses. There are some illiterate persons, such as weavers, tailors, shoemakers, etc., who require spectacles. There have been several engine-drivers who after operation have been restored to duty. In 1923 the percentage of failures recorded was 1.6 per cent.—1.2 per cent. from suppuration and 0.4 per cent. from hæmorrhage.

Many of the cases of suppuration were preventable. Some patients decamped to the bazar a few hours after the operation, others removed their bandages to have a look round or rubbed their eyes with dirty fingers. It is the after-treatment that is the difficulty. The patients behave well on the table. There are exceptions, but, as a rule, they are much less neurotic than Europeans. As an example, an old man brought his daughter to me for cataract extraction. (Probably her husband was willing to keep her only on condition that her father arranged to have her sight restored; but that is another story.) The woman had a child she was nursing and when she lay down on the table the old man took the child. The child cried so much that it upset the mother and I told the old man to give the child back to its mother. He did so, the mother put the child to the breast and I removed her cataract while she was feeding it.

With so many cataracts to treat, one ought to be able to have something to say about the cause of cataract. My experience suggests that the main cause is the glare of the sun. Bamdah is situated about 320 miles to the north-west of the Bay of Bengal, and the great majority of the cataract patients, and the other eye cases, come from the hot dry regions further inland, and comparatively few from the moister and cooler districts to the south-east. We have a saying in India that eye disease is in inverse proportion to rainfall. Cataract, at least, seems to become more prevalent as we retreat from the sea and reaches its maximum in the very hot and dry Punjab. Not much significance is to be attached to the fact that a large majority of the patients are men, for owing to social custom and physical difficulty women come to the hospital less readily than men. It would be interesting to know whether cataract is less common among the women who are confined to the *zenana* in India than among those who live an open air life; but on a matter of this kind it is difficult to get accurate information.

A very important point in cataract extraction is the sharpness of the knife. Any dragging on the wound is very likely to cause an escape of vitreous, and a ragged wound heals less quickly than a clean one. I send my cataract knives to Weiss in London for repair, for I have yet to discover any one east of Suez who knows how to sharpen a cataract knife. To keep the knife in good condition I rely on its being kept thoroughly clean and thoroughly dry. I have given up smearing the knife with vaseline or any other lubricant but I always clean the knife myself and, as the cataract knife is very often used for iridectomies as well as for cataract operations, it often happens that I do a hundred or more corneal sections with the same knife before sending it for repair.

There is a great field for ophthalmic surgery in India, and far from being exhausted it is just beginning to be reaped. When I go on

tour, I find scores of people blind from cataract in villages only a few miles from Bamdah, who have never realised that it is possible for them to have their sight restored. The number of such cases throughout the country must be enormous. It is worth while recording that this work has not in the least been interrupted or interfered with by the anti-foreign agitation of recent years. At the time when the non-co-operation movement was at its height, the hospital was fuller than it had ever been.

To conclude with a word on finance. The hospital is supposed to be supported by the Mission, but it would be nearer the truth to say that the hospital supports the Mission. It is open to all, but the patients are encouraged to give voluntary donations, and they do so very willingly. If one rupee were received for every operation, that would practically meet the outlay, and we are approximating to that standard. There are a few compulsory charges, as for private rooms, which are rented at from one anna to ten annas a day and spectacles are sold at a small profit. The District Board (which corresponds to the County Council in England), gives a grant of £40 per annum, so that altogether the income is more than the expenditure. To be explicit, the expenditure in 1923 was about Rs. 3,600 (including everything except my own salary, which should not be debited entirely to the hospital as I have to perform all the duties of a district missionary in addition to the medical work), and the local income was about Rs. 6,000.

EXCISION OF THE PINEAL BODY OF A MONKEY UNDER INTRA-ARTERIAL ANÆSTHESIA.

By J. P. ARLAND,

LIEUT., I.M.S. (T. C.),

Indian Station Hospital, Kirkee.

A LARGE adult red-faced monkey was placed on the table and the whole of the head and neck shaved. The right carotid sheath was exposed by an incision along the anterior border of the sternomastoid under infiltration anæsthesia. The common carotid was carefully dissected out. A clamp was applied to it in order to shut off the blood stream. The head was next elevated and the neck massaged in the direction of the venous flow. It was noticed at this stage that the internal jugular vein was in a state of collapse.

Twenty c.c. of a 2 per cent. solution of gum acacia containing $\frac{1}{4}$ gr. of cocain hydrochloride, along with 5 minims of adrenalin hydrochloride (1 in 1000) were slowly injected into the lumen of the collapsed artery.

The flow of the solution was indicated by the progressive blanching of the red-skinned head and face.

The internal jugular vein was now clamped.

After a lapse of 5 minutes the head and face were found to be completely anæsthetic.

Cushing's crossbow incision was employed, the transverse incision passing well over the occipital protuberance. The median incision was prolonged upwards for $2\frac{1}{4}$ inches. The incisions were deepened right down to the bone and the flaps retracted laterally. Emissary veins were stopped with Horsley's wax. Two small trephine holes were made, one on each parietal eminence. Two similar holes were next made $1\frac{1}{2}$ inch below each parietal eminence respectively and $1\frac{1}{2}$ inch from the median or sagittal line. A Gigli's saw was introduced and a square piece of bone was removed. Intracranial tension was diminished by puncture of the lateral ventricle. The dura

Shewing Pineal body between blades of forceps.

mater was carefully incised $\frac{1}{4}$ inch away from the longitudinal sinus. An aneurism needle was passed through the falx cerebri and the sinus ligatured and divided. The falx cerebri was cut right through and the inferior longitudinal sinus clamped and ligatured.

The cerebral hemispheres were gently retracted by thin copper spatulæ. The great vein of Galen was followed and the splenium of the corpus callosum was identified. The pineal gland was observed as a small greyish-yellow body immediately under the splenium. It was removed by forceps.

Observations.—

1. The anæsthesia was very sound.

2. The common carotid artery was clamped to shut off the blood current, in order to provide a bloodless field for the action of the anæsthetic. The presence of blood has a retarding influence on the power of the anæsthetic solution.

3. The addition of gum acacia combined with adrenalin increases the duration of the anæsthesia.

4. The internal jugular vein was clamped in order to lock in the injected solution as far as possible.

5. No signs of shock were noticed either during or after injection.

6. The monkey recovered.

TREATMENT OF HÆMORRHOIDS BY STRANGULATION AND SNIPPING METHOD.

By D. R. KEHAR,
CAPTAIN, I.M.S. (T. C.).

Indian Station Hospital, Landi Kotal.

DURING the last five years I have treated about three hundred cases of hæmorrhoids (external and internal) by the 'strangulation and snipping method' and have come to the conclusion that the results are efficacious and long lasting. The patients treated were from 14 to 50 years of age and the hæmorrhoids were in all stages of inflammation. I have tried all the methods given in the text-books, but the above mentioned method always took preference in my cases and gave very encouraging results. There is less danger of hæmorrhage from the ligature slipping. It is less painful to the patient, there is a minimum of bother to the operator and the help of an assistant is not required.

Technique.—The patient is given a good dose of castor oil the night before the operation and two or three soap and water enemata in the morning until no fæcal matter is passed. The patient is not given any food except milk twenty-four hours before the operation. The part is shaved, tincture of iodine and a T-shaped bandage applied.

Anæsthesia may be general or spinal. As soon as the patient is under the effects of the anæsthetic, tincture of iodine is again applied to the part and also about 6 inches around it. The anal canal is dilated with fingers and the piles are caught with a pair of Spencer-Wells' forceps or pile ring forceps, lifted up from the underlying structures and drawn out. Then a half-curved 1½ inch long needle threaded with No. 3 or No. 4 catgut suture about 16 inches long is passed through the base of the pile. The suture is drawn through the base of the pile to the extent of about 12 inches so that about 4 inches of it is left behind. These two ends are then tied round the half of the base of the

pile. This is the first strangulation suture. The small arm of the suture without the needle is held aside along with the pair of forceps in the left hand. The long arm carrying the needle is carried round to the other side of the base of the pile and passed through it and parallel with the first suture and as near to it as possible. The needle after having been taken out on the other side of the pile is passed through the loop thus formed by the long arm of the suture round the base of the pile and tightened. With the same ligature similar loop-sutures, two above and two below the base of the pile, are passed and tightened. These sutures will completely strangulate the pile. The small and the long end of the suture are then tied round the whole of the base of the pile. The mass within the bite of ligatures is snipped away with a pair of blunt-edged scissors. In this way all the piles are treated. An india-rubber tube 5 inches long is inserted into the rectum, sterilised vaseline smeared round the anal margin and dressings are applied.

After-treatment.—The india-rubber tube is taken out after 24 hours, the part is washed with warm sterile saline solution and the raw surface touched with the following solution every day:—

Tr. ferri perchlor.	1 part
Tr. opii	2 parts
Tr. myrrh	1 part

For four days the patient is given only milk and some astringent mixture to stop the action of the bowels. On the 5th day the patient is given one ounce of castor oil by the mouth and a rectal injection of two ounces of olive oil. The bowels act without any trouble. The patient can be discharged on the 7th or 8th day after operation.

This method is also useful in cases of partial prolapse with piles.

THE MIDWIFE IN INDIA.*

By C. C. MURISON, F.R.C.S.E., D.P.H., D.T.M.,
LIEUT.-COLONEL, I.M.S.,
Civil Surgeon, Belgaum.

BABY WELFARE is a very important subject in most countries but it is especially so in a country like India where special conditions have to be contended with. These conditions are innumerable and during this week you will no doubt hear many of them mentioned or discussed. In my opinion the one condition in India which has much to do with baby welfare is the "midwife," who has also much to do with the maternal welfare. She is in medical charge before, during and after the birth in a big percentage of the confinement

* Being a lecture delivered on 27th April 1925 during "Baby Week" at Belgaum.

cases. I have seen much of the results of the cruel and dirty methods of the indigenous *dhai* or untrained midwife in India and these methods are too revolting to be discussed here. Further, I do not intend to bore you with statistics but you can take it from me that the infantile and maternal death roll in their hands is high. The *dhai* in addition is responsible for the crippling and maiming of a big percentage of the mothers and infants. I am making these remarks not with the intention of blaming her; as she does her best in accordance with what she has been taught, but simply with the object of helping to devise means by which not only the infantile and maternal death rate but also the maiming and crippling of the infants and mothers in midwifery practice in India will be reduced to an absolute minimum.

India is a very conservative country, and the causes which contribute towards this state of affairs are chiefly religious and social prejudices and ignorance of the masses. These causes are difficult to overcome but in my opinion they can be conquered in a few years; provided, of course, all or some of the recommendations to be made are handled in a business-like manner; some of the remedies adopted for improving these conditions in the past have not been handled in such a manner, with the result that they are on the verge of failure.

The Government and various associations spend much money in getting Indian ladies trained and qualified as "midwives"; while the authorities of public dispensaries refuse to employ them, and if they have employed any of them they get rid of their services on various absurd grounds, for instance, one midwife's services were dispensed with as there was not sufficient work for her and the little work which had to be done could be done by a female ward servant.

This raises the question, "How are they to make a living?"

Many of you no doubt will say "Start a private practice." This is not an easy matter as, besides establishing herself in private practice, she has to compete with the indigenous *dhai* or untrained midwife who is already well established as were her mother and grandmother who most probably were also indigenous *dhais*. Further the charges of the indigenous *dhais* are so small that it is impossible for the qualified midwife on such terms to make a living.

The result of this is that we have great difficulty in getting candidates to come forward for training, and many of those who do apply for training are unsuitable and so the system by many is considered to be a failure.

In my inquiries about the non-employment of qualified midwives at dispensaries, I am informed that the chief reason is that there is not sufficient work for them. My conten-

tion is that this is a wrong way of looking at this subject, as the work will come and increase after a midwife has been employed, and not till then. The increase of work will be slow and gradual, and so the employment of a midwife should not be condemned until it has been tried for a few years.

The maternity wards of the Civil Hospital, Belgaum with its up-to-date appliances and a large staff of well qualified persons (as Civil Surgeon, lady doctor, other medical men, European and Indian midwives and nurses and also trained menial staff) has taken several years to increase its numbers of maternity cases as seen from the following figures:—

Year	1910	1911	1912	1913	1914	1915	1916	1917
Maternity cases	8	13	21	28	40	42	42	50
	1918	1919	1920	1921	1922	1923	1924	
	38	40	47	47	65	93	131	

Other patients, suffering from diseases or conditions connected with midwifery practice, have also progressively increased both amongst the out-patients and in-patients.

With the object of improving the maternity practice conducted by the indigenous *dhais* or untrained midwives the Government of most of the provinces of India have legislated for the training, examination and registration of midwives. The result of this is that there are now many registered midwives but this unfortunately, except in a few cases, has not affected the indigenous *dhais* who continue to practise midwifery in their old dirty and cruel methods. Therefore some measures should be taken to improve their methods.

I suggest that:—

1. All women including indigenous *dhais* who are practising midwifery without having passed an examination in midwifery and in the management of infants, and are not registered as a "midwife" with the authorised Nursing Association of the province should be enrolled.

2. All enrolled *dhais* should be put through a regular prescribed elementary course of training in surgical cleanliness, midwifery, feeding of infants, etc. at a midwifery hospital.

3. The elementary course of training should be prescribed by the authorities of these midwifery hospitals.

4. The period of this training should be about one month in a large hospital and longer in a small hospital. Therefore from a financial point of view it is preferable to train them at a large hospital.

5. The training depending on the available finances should be:—

(a) Free.

(b) Part payment by the *dhai*.

(c) Full payment by the *dhai*.

6. All *dhais* who have gone through the training should be styled "trained *dhai*" and be

registered as such with the authorised Nursing Association of the province, but separate from the midwives and nurses. The registration should be free of charge.

7. After a few years, say about five years, no indigenous or untrained midwife should be permitted to practise in midwifery, provided of course the local conditions permit of this suggestion being enforced.

8. If a midwife or trained *dhai* is not available in an area to replace an indigenous or untrained *dhai* at the end of the prescribed number of years, the authorities should consider the appointment of a midwife or trained *dhai* on a salary or part time salary.

9. In the course of time the indigenous or untrained *dhai*, and later the trained *dhai*, will gradually cease to exist, and then the normal midwifery practice, unless the customs change, will be carried out chiefly by the midwives.

I may here state that:—

(a) In the year 1902 I, as Residency Surgeon at Baroda, on being asked expressed views similar to the above and later was a member of a committee which selected indigenous or untrained *dhais* for this training.

(b) Dr. A. de Gama, Assistant Director of Public Health, Central Registration District, Poona, during the "National Baby Week" in Kirkee last year, suggested that all untrained *dhais* who were practising midwifery should be trained for about a fortnight in the elements of cleanliness and non-interference.

(c) In the *Times of India* of Saturday, 27th December, 1924, you will see that the Khaipur State last year had 49 *dhais* trained under the scheme for the improvement of *dhais* in Sind; 38 of these *dhais* appeared for the examination and 32 passed. The examiner who came from Multan made the following remarks:—"I was not only surprised but extremely pleased at the way most of them answered questions. It does their teacher great credit that they have learnt so much. They really seem to understand the evils of dirt and the value of cleanliness, and one hopes that superintendents will be forthcoming who will see that what has been learnt is put into practice, and also that the *dhais* who have been so willing to learn will be very much better paid than heretofore".

Now why cannot something of this kind be done in other parts of the country? Why not in Belgaum district?

The following two conditions are necessary to make the above mentioned recommendations to be a complete success:—

(a) Money.

(b) Legislation.

I am given to understand that the committee of this "Baby Week" has collected a very large sum of money and that a big percentage of it will not be spent, and so I ask the committee to consider the transferring of a large sum of

money to the Belgaum Indian Midwives' Association, whose object amongst others is to train Indian ladies at the Civil Hospital, Belgaum, for the midwives' and nurses' examinations held by the Bombay Presidency Nursing Association. The Belgaum Indian Midwives' Association has been established with the approval of the Government and it is managed by a committee of which the Collector of Belgaum is president and the Civil Surgeon is the Honorary Secretary and Treasurer. The accounts of the Association are audited by the Government auditors. It is quite possible that amongst you here there may be some who would like to follow the splendid example of His Highness the Mir of Khaipur, who gave a donation of Rs. 10,000 towards the midwives' scheme of Sind. Donations, contributions and subscriptions could be given to the Belgaum Indian Midwives' Association for the specific purpose of training these indigenous or untrained *dhais*, and later when the indigenous or untrained have all been trained, or are not forthcoming for any training, the money could be spent in training Indian ladies for the midwives' examination held by the Bombay Presidency Nursing Association as is being done at present.

"Baby Week" is being held with the object of improving conditions which affect the baby, and so I appeal to you all not to postpone important questions but to act in the matter immediately. For example, give money to the Belgaum Indian Midwives' Association to start the training of the indigenous or untrained *dhais* of Belgaum district as early as possible. I am confident that a large number of *dhais* will come forward for training as we have had many applications from them for training. The training of the indigenous or untrained *dhais* can be got through while legislation is under consideration and being obtained.

To make this scheme a success we must have legislation for enrolling the indigenous or untrained *dhai*, registering the trained *dhai*, etc. If legislation is not obtained then the scheme will be a failure as some of the indigenous or untrained *dhais* will refuse to be trained, and the system of having indigenous or untrained *dhais* will continue with its dangers.

Some persons are of the opinion that legislation will be cruel not only to the indigenous or untrained *dhais* but also to some of the public. I have considered this question from several aspects and I am unable to arrive at this opinion. This legislation will not be as cruel as the doing away with unqualified medical practitioners in the United Kingdom towards the end of last century. This was done by the unqualified medical practitioners having had to qualify by passing the ordinary professional examinations and getting registered as medical practitioners; and all this had to be done in the course of a few years. Those of them unable

to do this had to look in other spheres of life to make a living. On looking through the recommendations made by me it will be seen that they are not so drastic, on the contrary they are most considerate in every way possible.

This question of midwifery practice in India has to be faced with another great difficulty, and that is that a big percentage of the deaths among the mothers and infants during labour occur in the difficult and abnormal cases.

The present training which the midwives in India receive is based on that of the United Kingdom where all the midwifery cases attended by a midwife are within easy reach of medical practitioners who do much midwifery practice. In India the male medical practitioner does very little midwifery practice, and moreover the areas out of the easy reach of the medical practitioners are very considerable.

The training of the midwives and the "rules for the practice of midwives" enable the midwives to conduct only normal cases and compel them to be dependent on the medical practitioners in all the difficult and abnormal cases. In other words, in the areas within reach of medical practitioners the responsibility of the difficult and abnormal cases can be transferred from the midwife to the medical practitioner, but the question arises as to what is to be done in the areas out of the easy reach of the medical practitioner?

This demands a constructive and not a destructive criticism. I say this because I have been told that a midwife should not do more than conduct normal confinements. Then how is this difficulty to be got over?

The midwife, in these difficult and abnormal cases out of easy reach of a medical practitioner, is helpless, and this helplessness is due entirely to her training and the "rules for the practice of midwives." I know midwives who are quite capable of doing more than the rules permit them to do, but in an emergency they will be afraid to do their best, as a complication or a death may occur when they exceed their duty and then they will be liable to have their names removed from the register of midwives and this may mean ruin to the midwife.

With the object of making you realise the situation let us take an example of a difficult and abnormal case of labour in your family, in charge of a good midwife, at 2 A.M. in a country place out of the reach of a medical practitioner. Is this midwife to sit there and let the mother and infant die, or do something to save them? I am sure you will all say "do something to save them". How can she, when her training and the rules permitting her to practise midwifery prohibit her. It can only be done by her being trained for it, and the rules should be amended so as to let her act up to her training. This means that she should be trained to be an "operating midwife".

It has been argued that it is impossible to have a semi-qualified medical practitioner in the person of an "operating midwife," and so if such a person is required then a female medical practitioner of the standard of the L. C. P. S., with or without a midwife, should be employed. In my opinion this is also impossible as the female medical practitioner will neither practise nor accept a poorly paid appointment in the country districts. Further, her appointment meets the requirements of overcoming the difficult and abnormal labour case but she will not do any of the nursing duties. Consequently we must have someone who will not only do the nursing but also conduct the difficult and abnormal cases.

If the law can permit a midwife to practise midwifery, that is, to conduct normal labour cases then under the special conditions of India the law should be amended to permit an "operating midwife" to practise midwifery, that is to conduct the abnormal as well as the normal cases. Therefore we must consider the question of the qualifications for the "operating midwife".

The candidates for the L. C. P. S. qualification have to matriculate at an university or pass an equivalent examination and then undergo a four years' course of medical training, while a general hospital nurse and a midwife have to undergo respectively a three years' and a year's training. Taking these courses of training into consideration I suggest that the "operating midwife" should be intelligent, with a fair general education, and have gone through a four years' training briefly as follows:—

Medical and surgical nursing (including medicine and surgery more advanced than usual) in the first three years of training.

Midwifery including operations, etc.	} in the fourth year of training.
Midwifery, nursing and anaesthetics	

The training in midwifery should be such that they will or can always be independent of medical practitioners and especially so in India, as at present the male medical practitioner is very seldom called in to conduct a normal case. In short they should be able to cope with any emergency, including operations.

A few years ago the committee of a dispensary discharged a midwife, not because she was inefficient but simply because the "rules for the practice of midwives" prevented her from conducting the difficult and abnormal cases. They said that she was useless to them as they wanted a midwife capable of conducting the difficult and abnormal cases and thus independent of the male medical practitioner.

The next question which needs consideration is:—"Where and how are we to employ these trained *dhais* and midwives?"

Some of them will no doubt start a private practice, but what about the majority of them?

We must find them employment otherwise the whole of the scheme for training them will be a failure. In my opinion one or more midwives or trained *dhais* should be employed at every dispensary or hospital. It is absurd to expect menial servants to perform the work of midwives. It is neither fair to the midwives nor to the patients. These midwives and trained *dhais* should be available for district work. This means that a fund for the maintenance of these midwives and trained *dhais* should be established at these dispensaries and hospitals. The authorities of these dispensaries and hospitals will undoubtedly be pleased to establish the fund, and also contribute to the fund, but it is up to the public to subscribe liberally towards the fund and make it a success. The scheme should be so framed that the subscribers will get the services of a midwife or trained *dhai* at reduced rates while the non-subscribers should pay heavier fees.

The object of this lecture is to show the importance of this question in relation with baby welfare, and I hope that those concerned (on this occasion the Executive Committee of the "National Baby Week", Belgaum) will consider this subject and act further in it if convinced of its importance.

A PUBLIC HEALTH POLICY.

By W. C. ROSS,

LIEUT.-COLONEL, I.M.S.,

Director of Public Health, Bihar and Orissa.

THERE is a welter of misunderstanding with regard to the term "public health," and a confusion of ideas with regard to its needs and policy. Public health—in the correct sense of the term—is an inclusive entity which deals with all matters concerning the health of the individual, as well as of the community, and all that appertain thereto, and arise therefrom. Curative and preventive medicine, hygiene, legislation and administration, psychology, economics and finance all come within its scope and all demand study and balanced consideration. In contemplating public health policy and administration, it is necessary to take into consideration all these factors, otherwise the policy is likely to be crude, raw, and inapplicable, and the end will be failure.

Preventive medicine has been arrived at by a process of evolution from curative medicine, and is based upon the wider application of the principles of medicine and of general science to the benefit of the community as a whole, and not of the individual alone. It is, in effect, an altruistic application of knowledge to the general good, and it naturally uses all sources and sorts of knowledge in a wider and more general manner than was contemplated in the philosophy of general medicine in the past.

Nevertheless, although differing in essence and in application, both curative and preventive medicine have much in common and are founded upon the same bedrock of exact knowledge in many branches of science, and they cannot be separated altogether. There is always a tendency to administer in water-tight compartments and to separate entirely the branches of work which are in any way separable. This tendency is bad, and leads to inefficiency and overlapping and leaves too much to the controlling administrator, and too little to the co-operation and co-ordination of the activities of the branches of work concerned.

Curative medicine is the parent, and still keeps its hold too strongly on the public mind, because the individual patient expects individual benefit. In other words, the selfishness of the citizen is the stumbling-block to the development of public health.

Preventive medicine is the modern offspring—new, eager and with high ideals and aims. The lack of a communal conscience, and the weakness of public opinion in India have retarded its growth and postponed its development, and the lack of a policy, funds and organisation have prevented the possibilities of untold benefit to the people and the country. Curative medicine cures its tens, but preventive medicine can save its thousands; yet it is still neglected and ignored though the latent possibilities of its future are golden with promise.

Curative medicine has been organised on an extensive scale for many years and has its hospitals and dispensaries throughout the land. It has a large medical and subordinate staff and much money is spent upon it. Still there is a cry and a need for expansion. There should be at least one dispensary in every public police *thana* and there is great need of a better medical staff in the dispensaries. The rural dispensary is itself capable of much improvement; the equipment of drugs and instruments is grossly inadequate and too often the doctor in charge has forgotten much of what he ever learnt.

Better dispensaries and better doctors are necessary and it is no use improving the dispensary equipment before better doctors are available. The tendency to lower the standard of medical knowledge required to obtain a diploma must be stopped. The standard should be raised and not lowered. A good doctor with inadequate equipment can do much but the best equipment in the hands of a bad doctor is useless. The policy should, therefore, be to raise the standard of medical knowledge in the first place and to provide better equipment subsequently.

The need for medical relief in rural areas is very great, and is accentuated by the fact that most graduates and many licentiates will not practise in rural areas, but prefer to starve in the towns, and eke out a livelihood by means which should be beneath their dignity. The problem is partially an economic one and partially due to

the preference for work in a circumscribed area and under the most comfortable and convenient conditions. As a practical means of overcoming this difficulty, and inducing young doctors to start practising in rural areas, I would suggest a policy of subsidising suitable doctors in selected rural areas. A regular subsidy which would obviate the risk of financial failure and enable a doctor to settle in a rural area without the fear of being starved out, might enable many rural areas to obtain resident doctors. Such has been the policy adopted in the rural areas of Ireland for many years, and such a policy is free from much risk, or wasteful expenditure, and has great possibilities of success. I would suggest that provincial governments should give recurring grants to district boards for this purpose and that district boards should select the places where doctors would be most useful, and should select the doctors for the posts from a general list of suitable qualified medical men, to be maintained by the provincial government in the medical department.

Preventive medicine has not yet been developed or organised. Its future lies before it pregnant with promise as yet unfulfilled, but the hope of fulfilment is faint and far under present conditions. There is no royal road to success and there is no short cut to achievement. The first essential is to know the facts, the second to know what is wanted, the third to consider how to obtain it, and the fourth to arrange to get it. So far as we have got at present, we know only the facts—the sad fundamental facts of disease, sorrow and suffering. We know that epidemics ravage the land and that preventable disease causes untold suffering. What is wanted is a policy—a strong clear call to tackle the problem and to fight preventable disease. For this a leader is required, a real political leader whose aim is to relieve and benefit the body politic. There is no inherent difficulty in dealing with the situation. It only requires courage, selflessness, and steady determination. The facts are plain and simple and the policy may also be plain and simple. Legislation is required in order to create local authorities and to give them ample powers to carry out necessary preventive measures. Legislation is required to control the individual and to compel his respect for the rights and safety of others. The existing public health legislation is so defective, tentative and unsuitable that it might almost as well not exist for all the real good it does.

The next essential is a provision of funds. Nothing can be done without expenditure, and nothing will ever be done until the financial problem is tackled in a statesmanlike and courageous manner. It is idle to prate, in platitudes, of noble intentions for improvement. Money talks. Begin by arranging to provide adequate funds and continue by laying down a definite policy as to what is wanted, what is aimed at, what is

hoped for, and proceed then to carry it out and apply it.

I would suggest that the policy at first should be restricted to dealing with epidemic and preventable diseases, to the education of the community with a view to obtaining their understanding of, and co-operation in, preventive measures, and to the enactment of legislation to control the individual in matters affecting the health and safety of others, and to organise and direct the preventive measures required in dealing with epidemic and preventable diseases.

In the consideration of how to carry out such a policy it is obvious that a large staff will be required and that organisation will be needed—complete in detail and comprehensive in scope. Organisation is the basis of prevention, and anticipation is its aim and essence. Organisation implies staff and equipment and it must be based upon local knowledge of the villages, the roads, the language, the conditions of life, and the lives and minds of the people themselves. Good organisation, therefore, demands decentralisation, and must be carried out by local authorities, and not by a central administration.

The central administration should be concerned with such functions as those of co-ordination in administration, legislation, control, and financial assistance, maintenance of standards of staff, equipment and efficiency, inspection of work, advising as to appointments, rules, regulations, and working procedure, co-ordination between local authorities and the compilation of statistical records and returns, etc., etc. Local authority should vest in district and local boards, with ample powers such as they do not now possess. The staff should be founded upon a unit posted at every police station, because the returns and reports are brought to police stations by village *chowkidars*. Such a unit should consist at the very least of a literate compounder in charge, a trained disinfectant and two *domes*. It should be provided with panniers or boxes with an ample stock of disinfectants and vernacular leaflets of instructions and advice how to prevent and avoid epidemic and preventable diseases. A few safe and simple remedies, etc., may also be included. The village *chowkidars* should be provided with coloured post-cards with the name of the village and *chowkidar* on them, and addressed to the police station. If red cards are used for cholera, yellow for small-pox, blue for plague, etc., it does not matter that the *chowkidar* cannot read. Usually he will not be colour blind. He should post or send or deliver the correspondingly coloured post-card to the police station at once as soon as a case occurs, and he should get a reward of four annas for every notification received within 24 hours. The reward will stimulate prompt reporting which is essential to the success of preventive measures. The post-cards (endorsed at the *thana*) will also serve as vouchers for the payment of the reward. The procedure is simple and effective. On

receipt of such a notification, the unit should obviously proceed at once to the village and carry out preventive measures. The units must be co-ordinated and controlled by an assistant health officer in each subdivision, with a district health officer in general supervising charge. There is room for a larger staff. The staff suggested above is a working proposition on the minimum possible scale.

The district health officer should be a servant of the district board and must, therefore, work under the orders of the chairman, but it is essential that he should co-operate with the Civil Surgeon who is the government medical and health officer in the district, who has all the staff and equipment provided by Government, at his disposal, and who is in direct receipt of all reports of births, deaths and epidemics through the district police. With this end in view the Civil Surgeon should always be a member of the district board, and should be the chairman of the Sanitation or Public Health Committee with definite powers of control over the staff delegated to him by the chairman. If the general principle of decentralisation be accepted, as I have enunciated it above, this procedure is the only one by which the desired co-ordination can be obtained. The Civil Surgeon as Civil Surgeon is a Government official, and cannot officially control a district board staff, but as a member of the district board and in co-operation with the chairman, the Civil Surgeon as a medical man of experience and standing can successfully co-ordinate the activities of the district board medical and health staffs, and the government staff.

Proposals have been put forward in recent years for the amalgamation of the medical and public health staffs in districts, and an attempt has been made in the district of Gaya to carry out such a scheme during the last 4 years. The result in Gaya has been a failure, unqualified and absolute, and the District Board of Gaya has realised this, and is now engaged in modifying its scheme. I do not consider that it is either wise or practicable to combine two such functions. A whole-time doctor is required in a dispensary, or if not, the dispensary is not required at that place. Further the dispensary doctor as he is at present, will not travel round doing disinfection and preventive and propaganda work. He wants practice and fees, and if these do not offer, he prefers a peaceful life in his dispensary. In any case it is practically useless to expect him to do public health work.

Preventive work requires an energetic and mobile staff, and necessitates the removal of all temptation to private practice. In my opinion, private practice should be absolutely forbidden to all health officers and they should draw a compensatory allowance in lieu of private practice. If private practice is allowed, even under rules and in special circumstances, etc., the only certain result is that the public health duties of the staff will be neglected. If this view is

accepted it becomes impossible to amalgamate the medical and health duties and staffs, and it is necessary to provide for two separate staffs, but it is not necessary to carry such separation so far as to prevent the district health officer from working in co-operation and co-ordination with the Civil Surgeon, functioning as a district board member and chairman of the committee, and authorised by the district board to undertake the general supervision and control of their medical and health organisations.

The need for a strong public health policy and a well-organised executive district staff is very great. Epidemic and preventable diseases are the curse of tropical countries with dense populations, and the cause of the majority of the deaths and by far the greater part of the disease. They constitute the most potent factor in sapping the vitality, and reducing the working capacity of the population, and they affect in the most profound manner the prosperity and well-being of the population. Yet all the time they are preventable: and yet all the time little is done to prevent them. The cost is held to be prohibitive and the funds cannot be made available. Nothing but lack of courage and imagination can admit of such a view. Wise expenditure on the betterment of the public health is the best investment possible from the national point of view. The problem is fundamentally one in economics and finance, and requires bolder, braver and wiser treatment than it has hitherto received. The present state of affairs constitutes a "vicious circle" in which the people are too poor to pay for health, and they are poor because their health is bad. It is only by breaking the vicious circle, by courageously facing the necessary initial expenditure, that any real progress can ever be made. There is nothing more certain than that a wise expenditure can and will bring in a great harvest which will provide further resources for a greater expenditure. The occasion awaits the man!

A Mirror of Hospital Practice.

FOUR UNUSUAL SURGICAL CASES.

By J. B. HANCE, O.B.E., M.B., B.Ch. (Cantab.), F.R.C.S.E.,

MAJOR, I.M.S.,

Civil Surgeon, Dera Ismail Khan, N.-W. F. P.

THE following four cases which have been treated in the Civil Hospital, Dera Ismail Khan, are recorded as showing features which are both unusual and noteworthy.

CASE I.

N. K., Mahomedan, male, cultivator, aet. 60, was admitted to hospital on 15th September, 1923, complaining of a painful swelling of the left side of the abdomen, of 25 days' duration, and which

had been increasing in size steadily since first noticed.

Personal history.—As far as could be obtained, showed nothing of note, and beyond periodical attacks of fever, the patient stated that he had always been healthy, and had led an active life. He had once passed blood in his urine about 2½ years ago, after a strain in lifting a heavy load, but it had quickly passed and he had taken no notice of it.

History of present disease.—Twenty-five days before admission, patient had an acute attack of pain in his left lumbar region which was colicky in character and shot downwards into the left inguinal region. These attacks lasted for a few days, and during them urine was passed frequently, with scalding pain and in small quantities.

Case I.

JOHN WALKER & CO. LTD.

Soon after the pain commenced he noticed a small swelling in his left flank which had daily increased. He had not vomited, nor had his bowels been interfered with, but he was under the impression that the amount of urine passed had been less than usual since the pain and swelling had begun. What urine he had passed had been passed freely and without effort, and since the first few days of his trouble, the act of micturition had been unattended with any pain.

He had not lost flesh before the onset of the present illness.

Condition on admission.—Patient was a thin man of fair general condition, with tic-tack heart sounds and thickened tortuous arteries. The abdomen was distended and moved poorly with respiration, movement being confined to the right flank. Respiration was almost entirely costal.

Facies hippocratica was marked, and the patient was restless and anxious, but invariably reverted to the left lateral position where he appeared to obtain the greatest ease, lying curled up with the knees drawn up. Palpation of the abdomen revealed a rounded tense swelling extending from two fingers' breadth below the ensiform to the symphysis pubis, entirely filling the left flank and side of the abdomen and extending as far as the outer border of the right rectus muscle on the right side. The swelling was of the general shape shown in the diagram and a fluid thrill was obtainable from all parts of it through to the flank. There was no constipation. Patient stated that he was suffering from continual gnawing pain in the left loin and back, and was most comfortable when lying on the affected side. Temperature 98°F., pulse 96 and of poor quality.

Diagnosis.—The previous history of blood in the urine, the nature of the early colicky pain with diminished urine, and the site of the tumour, together with the persistent lumbar pain, all pointed to the kidney as being the main cause of the trouble and on these factors and on the fluid thrill obtained, a diagnosis of hydronephrosis was made, and operation decided on. As it was late evening when the patient was seen, and satisfactory artificial lighting was not available, the operation was postponed till the early morning of the next day.

15-9-23. *Operation.*—The usual preparation was made. During the night, the pulse had lost in character, and the rate risen to 104. It was accordingly thought advisable to give him continuous intravenous saline during the operation.

On anaesthesia (A. C. E.) being attained, the anaesthetist, Dr. S. D. Rieley, was of the opinion that the patient would not tolerate the embarrassment to respiration of the usual lateral position admitting of the lumbar incision. Extra-peritoneal access could, therefore, only be obtained through an incision in the left mid-axillary line extending from the 11th rib above to the iliac crest, whence it was prolonged forwards towards the antero-superior spine. Two nerves, the last dorsal and the ilio-hypogastric were seen and preserved, but a third, presumably the ilio-hypogastric, was inadvertently cut in deepening the incision. The peritoneum having been stripped forwards, a large swelling presented itself, on needling which, thin, semi-purulent fluid was withdrawn. The diagnosis having been thus confirmed, the swelling was incised and large quantities of thin pale watery pus gushed out under considerable pressure. In all three-quarters of a large bucketful of this fluid was obtained. On exploring the swelling with the finger, it was found that the tumour was bilocular, the inner loculus being thinner-walled than the outer, and constituting an enormously dilated renal pelvis, while the outer loculus was lined with extremely thinned out renal cortex. From the pelvic loculus an opening

admitting two fingers led into a widely dilated ureter, down which a stomach tube could be passed as far as the opening into the bladder, where its passage was obstructed.

The condition of the patient, and the fact that a secondary operation would obviously be necessary, alike precluded any attempt to investigate the nature of the obstruction. The cavity of the hydronephrosis was accordingly marsupialised to the wound in the parietes, the rest of which was closed by layers, drainage tubes were inserted and dressings applied, and the patient returned to bed.

An hour later the patient showed alarming signs of collapse, and was transfused with 16 ozs. of blood taken from the vein of a volunteer donor. Grouping was impossible, owing to the lack of facilities, and in view of the serious condition the risk of hæmolysis was taken. The effect, fortunately, was markedly beneficial, and the patient rallied.

A slight reactionary temperature, 100°F., occurred during the evening of the day of the operation and lasted as far as mid-day of the ensuing day, after which it gradually fell to normal. The pulse improved steadily, from 132 on leaving the operating table, and virtual disappearance an hour later, to a steady 102 throughout the second day, after which it fell steadily to normal limits.

Patient did extremely well until 28th September, 1923, the 14th day, when bronchitis supervened and the base of the left lung was found to be full of rales. The condition spread rapidly to the right base, with dyspnoea and signs of cardiac embarrassment. On 4th October, 1923, patient's relations removed him, against advice and on their own responsibility, in order that he might die in his house.

CASE 2.

K. M., a Mahomedan woman, æt 20, was admitted to hospital on 3rd October, 1923, suffering from absolute constipation of 3 days' duration.

Previous history.—For the past year the patient had felt a rounded moveable swelling between the umbilicus and the pubes. Four months previous to admission, she became pregnant, but aborted at the third month of pregnancy. About ten days after the abortion she noticed that her original abdominal tumour was increasing in size. For three days previous to admission she had suffered from absolute constipation, neither fæces nor flatus being passed. She vomited on taking anything by mouth, but spontaneous expulsive vomiting had not taken place.

On admission.—Patient was a thin undernourished girl. The face was drawn and anxious and she was in severe pain, which was colicky and spasmodic in character, causing her to draw up her knees.

Temperature 97.8°F., pulse 96, respiration 24.

The abdomen was much distended, the distension being general, and rendering palpation

extremely difficult. No localising signs indicating the site of the obstruction could be obtained. On vaginal examination the whole posterior fornix was flattened out by a tense cystic-feeling swelling, which displaced the uterus forwards and to the right. The cervix was softened and the os admitted the tip of the index finger.

Recto-vaginal examination did little further to elucidate, except to strengthen the impression that the pelvic mass was cystic. A rectal tube passed easily for 18 inches, and a high warm water enema was given slowly with the patient lying on her left side. This, with the exception of a few small scybala being returned unchanged, operation was decided upon.

Operation.—Under A. C. E. anæsthesia, by Dr. S. D. Rieley. A median sub-umbilical incision about 5 in. long was made, the rectus sheath incised, the rectal bellies separated and the peritoneum opened throughout the length of the wound. On inspection of the abdominal contents, it at first sight appeared that one had exposed a six months' pregnant uterus, the entire hypogastrium being filled by an elastic fluid-containing tumour. On attempting to retract the intestine for a fuller view, it was found that this swelling was situated *between* the layers of the mesentery of the small intestine, and on further investigation, that it extended retroperitoneally downwards into the pelvis, and to the left into the left iliac fossa where it completely obliterated the iliac colon. The cæcum, ascending, transverse and descending colon were much distended and the pelvic colon flattened and empty.

The tumour was tensely cystic to the touch, and on exploration with a needle and syringe a creamy fluid was drawn off. A diagnosis of chylous cyst was made, and the swelling being packed off with gauze, it was incised and evacuated. Unfortunately, the dish into which the fluid was evacuated was accidentally upset, and the quantity is, therefore, unknown. The cavity was packed with gauze and the abdomen further investigated for any further possible cause of obstruction. None being found, the cyst cavity was marsupialised and the obstruction having been relieved, by gentle milking of the descending colon, the abdomen was closed in layers, with a drainage tube in the cyst cavity and dressings applied and the patient returned to bed.

Temperature 98°F., pulse 102, respiration 30.

After coming round from the anæsthetic, the patient passed flatus by herself. Pituirrin 1 c.c. at once and eserine 1/100 subcutaneously 4-hourly were ordered, and saline and soda bicarb. by the rectum also 4-hourly.

She did well for 12 hours, passing flatus but no motion. At 1 A.M. the night following operation, however, the pulse suddenly failed. Patient rallied under pituitrin but complained of distension, relieved by the passage of the flatus tube, after which she slept. The pulse, however,

again failed at 7 A.M. and the patient failed to rally and died at 7-30. A post-mortem was refused.

The fluid evacuated from the cyst was sent to the Chemical Examiner, Punjab and to the Central Research Institute, Kasauli, whose reports are given below:—

Colonel H. M. Mackenzie, I.M.S., Chemical Examiner, Punjab.—"Centrifuged and microscopically examined. Only structureless debris can be seen. No cellular elements and no hooklets found. From the colour of the fluid and the description of the cyst, I think, it may be chylous."

Major L. A. P. Anderson, I.M.S., Assistant Director, Central Research Institute, Kasauli.—"The fluid appears to be from a chylous or pseudo-chylous effusion. It contains a high percentage of fat (about 9 gms. per cent.), and also albumose and coagulated protein. It contains no sugar. Microscopically it shows spored organisms—probably contamination from the bottle,—fat globules in large numbers, fatty acid crystals, granular debris and practically no tissue cells of any kind.

The absence of the latter is in favour of chylous as opposed to pseudo-chylous fluid, while the absence of sugar may be against chylous fluid, though in these fluids sugar is not always present."

Remarks.—It may perhaps be permissible to anticipate the obvious criticism that one should not have been content with simple relief of the obstruction but should have drained the bowel as well. Cæcostomy was discussed at the time, and my reliance on the plastic nature of the obstructing mass and on the stimulant effects of pituitrin and eserin on the freed bowel seems, on reflection, to have been an error of judgment, which though it gained time at the operation, may have lost me my patient. It seems clear that the bowels were so intoxicated by three days' obstruction, as to fail to respond to pharmacological stimuli, and that drainage of the cæcum might have remedied the condition.

It is intended to conclude all future operations for the relief of large bowel obstruction by a routine temporary cæcostomy, to avoid if possible this source of error.

It is with no intention of minimising this error of judgment that the conviction is, however, expressed that had skilled nursing, so essential in obstruction cases, been available, the fatal result might have been avoided. These late obstruction cases are the bugbear of the *mofussil* surgeon, and his more fortunate colleague in large towns has great cause to be thankful for his amenities. In the *mofussil* the surgeon is faced with a certainly fatal result if he abstains from interference, and the probability of losing his case from sheer lack of skilled nursing if he operates. It is, perhaps, not too much to hope that the time is approaching when the axiomatic truth will obtain general recognition in India, that it

is at least as important to provide a hospital with adequate nursing as to equip it with instruments and provide a surgeon.

CASE 3.

K. M., æt 60, Mahomedan, male, admitted to hospital on 21st March, 1924, complaining of swelling and ulceration in his left breast.

Previous history.—One year previously he noticed a swelling the size of a walnut in his left breast, which had been steadily increasing ever since. The patient had not noticed any loss of flesh, nor did he complain of any weakness. Enquiry failed to reveal anything in his mode of life likely chronically to irritate the affected region.

On admission.—Patient was a sturdy Pathan giving his age as 60 years, which appearances confirmed. By calling he was a cultivator. There was a hard swelling about the size of a pomegranate in the left breast, the nipple which was markedly retracted, forming roughly the centre of the swelling. There were two ulcerated areas, one on the medial and the other on the infero-external side of the nipple. The margins of the ulcers were irregular, rolled and everted, while their bases were covered with vascular granulations, bleeding freely on touching. The whole tumour appeared fixed to the underlying muscles. There were three enlarged indurated glands palpable in the pectoral division of the axillary group of the same side. The liver, right breast, right axilla and both supra-clavicular regions appeared free. Rectal examination negative, examination of the spine and long bone negative.

Operation.—On 24th March, 1924, radical excision of the breast, sternal portion of pectoralis major, axillary glands and pectoral fascia including abdominal deep fascia as far as the middle line below the ensiform cartilage, by Samson Handley's method. The flaps of skin would not entirely meet at the operation and an area about 1 inch square was left to granulate. On examination the tumour was found to involve the pectoralis major and, when cut, to give the typical "unripe pear" appearance and feel.

Progress.—Three days after the operation three stitches had to be removed to relieve tension on the flaps, leaving a larger granulating surface. Recovery subsequently was uneventful. It is most regrettable that, owing to the advent of the month of *Ramsan*, the patient declined skin-grafting, and left hospital at his own request for his home across the Border, with a clean granulating wound 3 in. by 2 in. and has not since been seen. Reports, however, from his fellow tribesmen received a few days before writing, six months after operation are to the effect that the wound has healed, and that the patient is in good health.

The appearance of the tumour and the glands on operation confirmed the clinical diagnosis of scirrhus carcinoma of the male breast, and the

entire tissue removed was sent to the Central Research Institute at Kasauli for pathological confirmation.

The report of Major L. A. P. Anderson, I.M.S., Assistant Director, is as follows:—"Sections of the tumour present the typical appearance of carcinoma. Involvement of the muscles has occurred at the edge of the growth, but sections of the more distant parts of the pectoral muscle showed no carcinomatous infiltration.

The glands are extensively involved, some of them consisting entirely of tumour material, with no evidence of lymphoid tissue at all."

CASE 4.

F. æt 22, Mahomedan, female, admitted into hospital on 5th July, 1923, complaining of swelling and ulceration of the left breast.

Previous history.—About a year previously patient had noticed a small swelling above and to the inner side of the left nipple. This swelling increased slowly in size until some 3 months later the patient became pregnant. During pregnancy the increase in the size of the tumour became very much more rapid. The swelling softened in two places which were opened, by a native barber, with a slight discharge of thin fluid. The patient had had a child some ten days before admission and with the onset of lactation a further increase of the swelling had taken place and she had come for relief of the dragging sensation and the throbbing pain in the breast. The child was fed entirely from the right breast.

On admission.—The left breast was enormously enlarged being at least double the size of the right lactating organ. On each side of the nipple were two ulcerating areas with irregular edges and unhealthy looking bases exuding a thin watery fluid. The edges of these ulcers were irregular, and, in the case of the inner one, undermined.

The skin was of a typical *peau d'orange* appearance, with a general erythematous blush but below the nipple was a small patch 1 in. by $\frac{1}{2}$ in. where the skin was shiny and much discoloured and which gave fluctuation. The nipple was slightly but definitely retracted, but was not "deviated" upwards and to the left. The tumour, as a whole, appeared to be freely moveable on the deeper structures. There were enlarged glands palpable along the axillary border of the pectoralis major.

There were no enlarged glands in the neck or supra-clavicular regions. The liver and right breast and axilla appeared normal and the right breast was lactating normally; and a recto-vaginal examination was negative, as was examination of the spine and long bones. Temperature 99.4°F. , pulse 92, respiration 18.

Diagnosis.—The appearance of the breast at first sight suggested acute cancer (mastitis carcinosa).

Neither the appearance of the breast nor patient's condition suggested the acute suppurative mastitis of lactation. The softened area and the appearance of the two ulcers threw doubt upon this view, but did not definitely negative it, and suggested a sub-acute inflammatory—probably tuberculous—mastitis, aggravated by lactation: an impression strengthened when one of the ulcerating areas was found to mask a sinus admitting the probe for $1\frac{1}{2}$ in. The glands in the axilla would fit either alternative.

Other, but, less probable, alternatives were sarcoma, with glands in the axilla secondary to infection of the ulcers, and actinomycosis—ruled out by the absence of ray-fungus in smears taken from the sinus.

Operation having been accepted, it was decided to explore the swelling, on the table; and to be guided by what was found.

Operation.—On 6th July, 1923. Temperature 98.6°F. , pulse 88, respiration 18. Under chloroform anaesthesia. The form of anaesthesia is to be regretted, but the services of an anaesthetist familiar with the administration of ether at high temperatures were not available. The softened area was isolated by swabs, and incised, and about 3 drachms of creamy pus containing cheesy granules evacuated.

This seemed to tip the balance in favour of tuberculous mastitis and the cavity was swabbed with iodine and plugged with gauze. Some doubts as to the nature of the tumour remaining in the mind of the operator, the incision of Samson Handley was made from the lower edge of the insertion of the great pectoral slightly convex downwards, ringing the tumour, and downwards and inwards to the linea alba below the ensiform. Skin flaps were undercut and removal of axillary fat and breast from the deep fascia proceeded with. At this stage there was a little difficulty in detaching the breast from the deep fascia, where several cord-like attachments were encountered, which engendered further doubts of the simple nature of the tumour, and only the anaesthetist's report prevented the operation being turned into a radical excision of the breast with pectoralis major.

The patient, weak at the commencement of the operation, was shewing signs of further weakening, and the anaesthetist wished as speedy a termination as possible. The simple operation was, therefore, completed, not without severe misgivings, the axilla drained, dressings applied and the patient returned to bed.

The misgivings during the operation were largely mitigated by subsequent examination of the tumour and axillary glands. The former presented multiple caseating foci between which were interspaced areas of fibrous tissue and of apparently healthy breast tissue, while the latter showed extensive caseation. The specimen, as a whole, was despatched to Kasauli for a pathologist's report.

Pathologist's Report.—Sections of the breast show numerous typical giant-celled systems of tuberculosis. There is a fair amount of fibrosis of the breast. The glands show the same changes in a minor degree.

Progress.—The feeding of the child from the right breast was prohibited for 48 hours to allow of recovery from the anæsthetic. Here a tribute must be paid to the marked devotion—amounting almost to maternal instinct—of the theatre compounder, Mahomed Khan, who developed a sudden and most unexpected aptitude for humanising cow's milk. For 48 hours the child was bottle-fed 3-hourly and the preparation of the milk and the sterilisation of the bottle were voluntarily undertaken by this compounder, whose concern with operation cases normally ceased with their removal from the theatre.

That the experiment was a success—surprising enough to anyone experienced with attempts at artificial feeding among the Indian peasant classes—is solely due to the devotion of this man—to a female child.

Glucose-soda-bicarb-saline was freely administered to the patient during the first 48 hours, after which feeding from the right breast was cautiously resumed. Drainage tubes were replaced by rubber-dam in the axilla after 72 hours and the wound allowed to heal. Recovery was uninterrupted and the patient and her child left hospital on 5th August, 1923.

Remarks.—Samson Handley (1923), whose knowledge of the subject is unsurpassed, says of tuberculous mastitis that it is "a rare disease accounting for only about 1 per cent. of hospital admissions for mammary disease."

This writer further says that in 50 per cent. of cases it forms the only discoverable form of tuberculosis in the whole body.

The case under consideration certainly revealed no other. It also presented several features not in accordance with the usually accepted description of this condition—e.g., the enormous size of the breast (probably due to the super-imposed lactation of the intervening healthy breast tissue) and the general erythematous blush. At the operation the most impressive feature was the firmness of its deep connections with the deep fascia. These unusual features would seem to suggest the possibility that, in Indian patients, in whom tuberculous lesions notoriously tend to a greater relative acuteness and severity than in the European, it is a condition relatively more to be reckoned with. The case under report is certainly an illustration of the wisdom of the procedure advocated by Handley:—Exploration of doubtful breast-swelling on the table prior to deciding between the radical and simple operation.

APPLICATION OF EXTENSION IN CASES OF SIMPLE FRACTURE.

By P. C. DUTTA, M.B.,

House Surgeon, Medical College Hospital, Calcutta.

THE procedure most commonly adopted for applying extension in the so-called cases of "simple" fractures and in most cases of compound fractures is to stick the adhesive plaster either directly to the skin or over a flannel bandage, but neither of these methods proves satisfactory. In the former blisters and sores are the rule, and in the latter, either the bandage slips and hitching against some bony or soft part produces a sore there, or the part below becomes swollen, œdematous and painful.

This led us to think of applying some other form of extension where the bandage will not slip and at the same time extension will not be applied directly over the skin. Firstly, we tried extension from a case of plaster-of-Paris, from a little above the site of the fracture to the required extent below. But this did not prove satisfactory. Then at the suggestion of Lieutenant-Colonel F. P. Connor, I.M.S., I tried the following method with very satisfactory results.

The limb being shaved is painted with glue (the formula is only a slight modification of Sinclair's—the proportion of water being 30 parts, which I thought would be most suitable for this climate); over this a flannel bandage is applied from a little above the site of the fracture to the required extent below. This bandage is thoroughly smeared with the same glue and extension is applied with two strips of flannel or adhesive plaster over the bandage. If flannel strips are used they are smeared with the glue and then applied over the bandage. I think flannel is better and sticks more readily over the moist bandage than adhesive plaster, and I have often used the former in the American method. Over this another bandage, preferably flannel (which can again be used in another case), is applied a little beyond the upper and lower limits of the previous one.

We found the following advantages in this method:—

1. Extension does not slip.
2. The bandage over the skin does not get loose nor slip down.
3. The extension strips not being applied directly over the skin, blisters and sores do not form.
4. Sufficient extension can always be applied.
5. The inner flannel bandage which is soaked in glue, when dry becomes very hard and acts much like a proplastic splint.

One modification which I generally adopt is to apply an elastic bandage for 24 hours at the site of the lesion, reaching well above and below it. This prevents any œdema being formed and causes it to disappear if it is already present.

If extension is applied while this œdema is present it is sure to slip, form blisters, etc., when the swelling subsides.

This method was mainly tried in cases of fractures of the femur, with satisfactory results. The only drawback is that if the knee or elbow is included in the glue-saturated bandage, no proper movement to these joints is allowed when the bandage gets hardened. But this can be avoided by not applying glue at the site of the joints, putting plenty of cotton-wool or simply moistening the part with little water before movement is applied.

ACRIFLAVINE IN OTORRHOEA.

By SHIAM NATH CONSUL, B.Sc., M.B., B.S.,

Jaipur City.

THE treatment of a case of chronic otorrhœa is, indeed, a very ticklish problem to deal with both in hospital and in private practice. It very often tires out the patience of the sufferer as well as the doctor.

In private practice the use of somewhat irritant ear drops, such as boric acid, spirit drops or other spirituous preparations is very difficult and often not possible with many weak and nervous patients after they have once had an experience of the drug.

Naturally under such circumstances one is obliged to use H_2O_2 (hydrogen peroxide), carbolic glycerine or some other ear drop which is both antiseptic and sedative.

In certain cases no doubt this routine treatment is successful in stopping the discharge and alleviating the suffering of the patient, but in most of the cases, especially those of long duration, marked improvement in a short time cannot be obtained by these methods.

For chronic otorrhœa or otorrhœa which has been recently started I have been using a $\frac{1}{2}$ per cent. solution (grs. ii to 1 oz.) of acriflavine in distilled water, and I have found it to be very useful.

The discharge is very appreciably diminished on the very first day and in about a week or 10 days ceases altogether.

I tried the solution on 12 cases, and in 4 cases I found that the discharge stopped altogether within the first week of treatment. In each of these 4 cases, I also know that the discharge has never occurred again up till now. I can only conclude that the others have been cured because they never returned to me after a week. The discharge had diminished to a very great extent when they left off treatment.

The special reason which has prompted me to place this fact before the medical world is that others may also have the opportunity of trying the drug and confirming the efficacy of the same themselves.

If this is proved to be a potent ear drop, I am sure, it will be a very great boon to the

humanity which is suffering from chronic otorrhœa.

Acriflavine fulfils three essentials of a good ear drop, i.e., it is a strong antiseptic, non-irritant and sedative.

The way in which I have been using the drug is as follows:—

(1) The meatus is first syringed out and the pus removed. Then it is further cleansed by instilling a few drops of hydrogen peroxide.

(2) The cavity is next swabbed dry and

(3) a few drops of acriflavine solution are dropped into the meatus with a dropper and a plug of cotton-wool applied.

Once a day usually suffices.

Next day one is apt to find a marked diminution in the amount of discharge and probably it will not be necessary to syringe the ear.

If this course of treatment is followed marked improvement occurs in a few days.

The treatment certainly encroaches to some extent upon the time of a busy practitioner, but its results are decidedly favourable and worthy of trial.

In 11 cases out of 12, I met with uniform results; but in one case where the otorrhœa was also associated with severe eczema of the ear, I found that frequent instillations of acriflavine proved somewhat irritant to the eczematous area which became swollen. However, on reducing the drops to once a day the condition improved.

The solution of acriflavine in the strength indicated is quite non-irritant, but it stains the clothing and the skin if clumsily dropped into the ear, hence it is very necessary to plug the ear after the acriflavine drops are used.

RETENTION OF URINE DUE TO HEMATOCOLPOS.

By MAQBUL ALAM,

*Sub-Assistant Surgeon, Taungdwingyi,
Dist. Magwe, Burma.*

MA KUN, a Burmese girl of about 16 years of age, was brought to the Taungdwingyi Hospital at 10 P.M. on 3rd February, 1925, with a big swelling and pain in the lower part of the abdomen and inability to stand or walk. She stated that she had not passed urine for 4 days. The patient was bed-ridden and had fever. She was treated outside in her village by Burmese physicians, but obtained no relief. One qualified midwife had also tried to pass a catheter before the patient was brought to the hospital but had failed.

On arrival at the Civil Hospital, the patient was put to bed, cleaned up and examined. There was a soft fluctuating swelling in the middle of the lower part of the abdomen, extending up to the navel. The flanks were not occupied. The girl was said to be a virgin and the duration of the disease was stated to be only 4 days. On auscultation no foetal heart and uterine sounds

were heard, so that pregnancy and the other uterine tumours were excluded.

On examination of the external genitalia there was a soft cyst-like tumour protruding outside the vagina, which was ecchymosed with prominent small blood vessels on it. It was larger than a duck's egg.

The meatus of the urethra was not visible. There was some dribbling of urine, as her *longyi* was damp.

On digital examination, I was surprised at not being able to find the vagina. The outlet was entirely blocked by the tumour. Thus I was sure that it could not be a prolapse of the bladder and the anterior wall of the vagina. I tried to push the tumour inside in order to expose the urethral orifice and succeeded in passing the catheter. I drew out 24 ounces of urine. The pubic swelling which extended up to the umbilicus disappeared, proving that this had been a distended bladder. The soft swelling which was protruding out of the vagina remained just the same. On palpation from the top of the tumour, my fingers could not feel any vaginal walls.

Having evacuated the bladder I gave an enema and she passed a good stool. She had not passed any stool for 2 days. Even now the swelling remained just the same, projecting outside the vulva. In the evening again a catheter had to be passed to relieve the bladder which was again distended. On further examination no other general disease was detected, except a slight rise of temperature. Her breasts were fairly developed, which was taken as sufficient evidence of having a normal uterus, though this, like the vagina, could not be felt. She gave no history of the commencement of the menses, but on enquiry, she confessed to having had unusual pains over the back a few days ago.

A diagnosis was made that the thick layer (tentorium) which entirely obliterated the vaginal orifice was a very thick imperforate hymen and that it protruded because of the pressure of the menstrual blood from behind it. An incision was made, which was enlarged afterwards on all sides, and about 8 ounces of retained menstrual blood came out; this contained some small clots. Menstruation continued for another 2 days.

The vagina had dilated much due to the constant plugging by the menstrual flow. The vagina took about 4 days to regain its elasticity.

The uterus and ovaries were now palpable and appeared to be normal. She was unable to walk for 2 days after the slitting of the hymen. She commenced walking with her back bent, due to pressure on the pelvis, on the third day. She was able to micturate freely after this and there was no retention of urine.

She was discharged cured on 8th February, 1925. The interesting points in the case are:—

(1) A thick hymen in a grown up girl of 16, is rarely seen in Burma.

(2) The collection of menses behind the hymen, which was causing retention of the urine, had to be diagnosed from various other conditions.

AN UNUSUAL FORM OF PSEUDO-HERNIA.

By A. BAYLEY DE CASTRO,

Junior Medical Officer, Haddo, Port Blair.

A POLICE-CONSTABLE (No. 3283) of the Andaman and Nicobar Military Police, had apparently been suffering from colicky pains in the stomach, and was advised by his friends to try cupping with his brass *lotah*. As the idea appealed to him, he lost no time in putting theory into practice.

At 8-30 A.M., on the 1st March, 1925, he set a light to some oil in the *lotah*—which was of 4 pints capacity—and applied this over the umbilical region of the abdomen. At 9 A.M., he tried to remove the *lotah* but found to his great surprise that he could not do so. Manipulations were carried out by himself and his friends till 10-30, when the pains becoming very acute, my assistant, Mr. Naidu, was sent for from the Haddo Hospital. He resorted to the first and well-known expedient of letting in some air, and to do this, he bored a hole in the bottom of the *lotah*, but nothing happened. Finally, the man was brought up to the operating room and I was summoned. It was now 11-30 A.M.

I found the *lotah* firmly stuck to the abdomen in the umbilical region. The skin of the abdomen was drawn very tense and puckered up all around the outer rim of the lip of the *lotah*, and so great was the tension that the patient could not lie on the broad of his back. He lay on his side with his knees drawn up to help relax the tension. His expression was very anxious, his forehead was bathed in perspiration, and the pulse was 132 per minute.

He was laid on the floor on his right side, a block of wood was placed under the *lotah*, and after the administration of chloroform, the *lotah* was cut through at its widest circumference with a carpenter's chisel and hammer.

On removal of the base there was revealed a mass which occupied $\frac{2}{3}$ of the interior of the *lotah*. This mass was dark-blue in colour, so thoroughly was it engorged with blood, had blebs on its surface, and felt solid in consistency. Taxis was tried but was absolutely useless; the mass could not be coaxed or in any way expressed through the neck of the *lotah*.

I thought that the herniated area contained, besides the abdominal wall, at least some omentum, if not a loop of gut.

I now made a crucial incision, down to the sheath of the rectus abdominalis in the middle line, and laterally down to the base of the mass. The nearest of the four pieces thus made was now picked up and all the congested blood and serum squeezed out of it. This piece was then

slipped through the neck of the *lotah* and immediately the latter fell off.

The hernia consisted of the entire thickness of the abdominal wall alone. The measurements of the abdominal wall caught up inside the *lotah* was five by six and a half inches, while the area affected up to the outer lip of the *lotah* was seven by eight and a half inches.

As the agency of strangulation was something I have never seen recorded before, I have been prompted to publish these notes.

I must acknowledge that at first I was a bit puzzled about the technique to be adopted in this case.

The patient made an uninterrupted recovery, the wound healed by first intention.

AN INTERESTING SIGN IN RETRO-CÆCAL APPENDICITIS.

By A. G. TRESIDDER, M.D., B.S. (Lond.),

MAJOR, I.M.S.,

Surgeon to His Excellency the Governor of Bombay.

So much has been written on the subject of appendicitis that it would seem almost impossible to note anything new in the symptomatology of this disease. A case, presenting a physical sign which I have not previously observed or seen described, having recently come under my care, I think it may be worth describing the case in some detail.

P. J. M., a Goanese, aged 17, employed as a cook at Government House, complained of pain in the abdomen, of 18 hours' duration, during which period he had vomited three times. On arrival at the dispensary, he was examined by my assistant, Mr. C. M. E. Warner, and it was noted that his pulse rate was 90 per minute and his temperature was 100°F. When seen by me about half an hour later, the patient was lying on his abdomen and on being questioned he explained that he found that this was the most comfortable position in which he could lie. There was some superficial tenderness on pinching up the skin just below the spino-umbilical line, the abdomen was slightly distended and there was pain on deep pressure over the right iliac fossa; there was no rigidity. Rectal examination revealed some tenderness high up to the right but no swelling could be felt.

A diagnosis of acute appendicitis was made and the abdomen was opened through the right rectus muscle. The appendix was found to be in the retro-cæcal position and attached in its entire length to the posterior aspect of the cæcum by strong adhesions, obviously the result of previous inflammatory attacks. The appendix appeared to be embedded in the posterior wall of the cæcum and it was found impossible to effect its separation without first dividing it at its origin from the cæcum. This was done, the stump invaginated and then the body of the appendix was dissected off the posterior aspect of the cæcum. It was embedded in a mass of dense

adhesions, its proximal two-thirds being much swollen and congested while its distal third was acutely kinked on the rest of the appendix, the portion distal to the kink being bulbous and gangrenous. After its removal, incision of the bulbous distal end showed it to contain about half a teaspoonful of brownish and very offensive fluid.

The patient made an uninterrupted recovery.

Such a state of affairs is, of course, quite common in retro-cæcal appendicitis; but the interesting point in the case is the position adopted by the patient, i.e., lying flat on his face and abdomen. Presumably the adoption of this position would allow the cæcum to fall forward and away from the inflamed retro-cæcal appendix, and in doing so, relieve to some extent the pressure on that organ.

In conclusion, I have to thank Major A. N. Thomas, D.S.O., I.M.S., Civil Surgeon, Mahableshwar, for his valuable assistance both during the operation and afterwards.

A CASE OF OBSTRUCTED LABOUR BY AN INTRA-UTERINE TUMOUR.

By M. N. S. CHETTI, L.M. & S.,

Civil Surgeon, Sagaing.

A BURMESE woman about 37 years of age, a multipara with five previous births, was admitted on 15th March, 1925, with severe and continuous labour pains and a history that she had been in pain for the last five days and had lost some blood at home; she had been attended by a Burmese midwife.

On admission her general condition was good. On making an examination per vaginam, a soft tumour about the size of a small coconut was felt in the pelvis—on pushing the tumour to one side there was just enough room for one finger to pass beyond it. On further examination it was observed that the cervix was fully dilated, that the membranes had ruptured and that the head was obstructed in its onward passage by the tumour. The tumour at first appeared like a reduplicated placenta which had been separated prematurely and, as the foetal heart was faintly audible, traction was applied on the tumour; it was found to be firmly fixed to the inner surface of the posterior wall of the uterus. It appeared as if the margins of the folded up placenta were tightly caught between the foetal head and the pelvis higher up, so forceps were applied with the object of extracting the head and the tumour together; this was found impossible. Then the tumour was removed at the level of the posterior portion of the dilated cervix and the child was delivered easily and alive. On introducing the hand into the uterus the placenta was felt distinct and loose and was removed entirely.

The mother and the child did well and left the hospital on the 14th day.

The tumour was sent for sectional examination. The report said that it was a malignant tumour,—a myo-sarcoma—which was likely to recur.

Aug., 1925.]

Indian Medical Gazette.

AUGUST.

PREVENTION OF TUBERCULOSIS IN CHILDREN.

M. LEON BERNARD and his colleagues have presented a report to the Academy of Medicine of Paris which is of the greatest importance in connection with the tuberculosis of children.

The report deals with the results obtained by a charitable organisation which has aimed at removing infants and young children from homes in which one or both parents are tuberculous.

When a pregnant woman is found to be tuberculous, arrangements are made for placing the newborn infant in a healthy home immediately after birth.

The infants suffer to some extent during the first year owing to artificial feeding, but after that they are quite up to normal standards. In no case among 123 children was congenital or acquired tuberculosis seen, but there was a rather high mortality during the first year of life reaching as high a figure as 38 per cent. in the first three months in one group of infants, but in most cases it was about 12 to 13 per cent. The causes of death were progressive wasting bronchopneumonia and infectious diseases of various kinds, and it is believed that the placing of the infants in groups is not the best means of dealing with them.

In children who had already become infected with tuberculosis from their parents it was found that if the disease was rapidly progressive removal to healthy homes caused a complete arrest of the disease in most cases. The mortality from tuberculosis among 171 previously infected children who were removed from their homes was only 7.6 per cent.

Infected children who were left with their parents usually died of tuberculosis within a short time, the mortality among them being 82 per cent.

Even when good home hygienic conditions prevailed, children left with tuberculous parents almost invariably succumbed to the disease so that it is evident:

- (1) That mild tuberculous infection in infants can usually be arrested by removing the children from the source of infection.
- (2) That persistent contact with tuberculous persons is almost invariably fatal for children.
- (3) That congenital tuberculosis is so rare as to be a negligible factor.
- (4) That inherited predisposition to tuberculosis is of little moment.

It is not likely that much can be done at present in India in the way of removing children from infected homes, but if a knowledge of the facts

is spread there is a possibility that many infants may be saved from inevitable destruction by persuading the parents to send them to uninfected relatives or friends who are living in healthy surroundings and who have no other young children in their homes. A child with arrested tuberculosis is not likely to be a source of danger to other children and it is likely that such a child will be, to some extent, immune, and in later life will have a greater power of resisting the chance infections to which most people are exposed from time to time than a person who has been entirely free from tuberculosis throughout the years of early life.

It is not suggested that infants should be deliberately exposed to infection for the purpose of acquiring this immunity, it is pretty clear that if we do our utmost to keep a child away from infection its chances of escaping the disease will be far greater than if it is allowed to come in contact with tuberculous persons.

The results obtained by the French workers are of great importance in demonstrating that it is usually by repeated infection or by intense infection that fatal tuberculosis is conveyed: if children are removed from the source of gross infection they have an excellent chance of survival, however bad their heredity may appear to be.

THE TRANSMISSION OF DENGUE FEVER.

CLELAND and BRADLEY in 1916 demonstrated that the *Stegomyia* mosquito (*Aedes aegypti*) is able to convey dengue from man to man and that a number of *Culex* mosquitoes tested by them did not convey the disease; their work did not clear up the important question of the period of incubation of the virus in the mosquito.

This problem has now been solved by the admirably conducted experiments of Lieutenant-Colonel Siler, Major Hall and Major Hitchens of the United States Army Medical Corps.

A clear and convincing preliminary report of their work appeared in the *Journal of the American Medical Association* of April 18th, 1925. The first successful experiments in the insect transmission of dengue were by Dr. H. Graham of Beyrouth in Syria in 1903, who reported that he had conveyed the disease to several persons by the bite of *Culex* mosquitoes which had bitten dengue patients several days previously. It now seems to be likely that Dr. Graham was working with *Stegomyia* mosquitoes as well as *Culex*.

Ashburn and Craig's single successful transmission of dengue by a *Culex* mosquito in 1906 has always seemed rather unconvincing as an outbreak of dengue existed at the time of the experiment; the precautions against accidental infection by wild mosquitoes were by no means infallible, and several other experiments carried out at the same time gave negative results.

Cleland and Bradley in 1916 demonstrated quite clearly that *Stegomyia* mosquitoes are capable of conveying the disease from man to

man and their work had hitherto been the only source of accurate knowledge of the insect transmission of the disease. The experiments of Siler, Hall and Hitchens constitute an important advance in our knowledge of dengue and therefore deserve special notice.

The work was carried out in a specially constructed experimental ward of the Sternberg General Hospital at Manila. The *Stegomyia* mosquitoes were bred out in the laboratory, and were allowed to feed by day (9—11-30 a.m.). *Culex* mosquitoes were bred from eggs collected in stagnant pools and were fed by night as they did not feed readily by day; they were more erratic in their feeding habits and shorter lived in captivity than the *Stegomyia* mosquitoes. Extraordinary precautions were taken to prevent accidental infection of the subjects of the experiments by outside mosquitoes, and the volunteers who were selected were recent arrivals in Manila, they had not suffered from dengue previously so far as could be ascertained. They were kept strictly confined in the mosquito-proof ward for 8 to 15 days before being bitten by the experimental mosquitoes and until the end of the experiment. Of 42 volunteers 25 were infected with dengue by the bites of infected captive *Stegomyia* mosquitoes. The negative experiments are not dealt with in the report under review. The incubation period of the disease varied from 4½ days to 7 days in susceptible persons, it never exceeded ten days in any case. The result obtained may be summarized as follows:—

- (1) Dengue fever was produced experimentally in 25 out of 42 volunteers by the bites of infected *Stegomyia* mosquitoes (*Aedes aegypti*, formerly known as *Stegomyia fasciata*). From 2 to 43 infected mosquitoes were used in each of the various experiments.
- (2) The blood of persons suffering from dengue is infective to *Stegomyia* mosquitoes which bite during the first three days of the illness.
- (3) *Stegomyia* mosquitoes which had bitten infective persons from two to ten days previously never conveyed the disease, while mosquitoes which had bitten eleven to sixty-six days previously did convey the disease in 25 cases. The incubation period of the virus in *Stegomyia* mosquitoes was therefore about 11 days under the conditions existing in Manila.
- (4) The mosquitoes which had become infective remained so up till 66 days and presumably they remain infective for the rest of their life.
- (5) Five persons were bitten by *Culex* mosquitoes (*C. quinquefasciatus*) under similar conditions, but remained free from dengue. All of these subsequently developed dengue from the bites of infected *Stegomyia* mosquitoes. *Culex* mosquitoes under the conditions of the

tests were therefore incapable of conveying the disease.

- (6) Twelve persons who had suffered from dengue from 41 to 121 days previously were inoculated with 0.5 c.c. of blood taken from dengue patients during the first or second day of the illness. Seven of these were refractory and the five who developed dengue had attacks of an average duration of 2.8 days as compared with an average duration of 4.8 days in their previous attack. An attack of dengue gives rise to partial or complete immunity for six weeks to four months.

This recent work brings dengue more definitely into line with yellow fever and it becomes more and more surprising that no spirochæte should have been satisfactorily proved to be associated with dengue.

The disease in which Couvy found spirochætes was not typical dengue. The relationship of the virus of dengue to that of sandfly fever is another problem which has to be worked out: it is assumed that the two diseases, though very closely related to each other, are specifically distinct, but so far as is known no conclusive differences have been demonstrated.

It is important to test whether the virus of dengue can be transmitted by sandflies and whether the virus of sandfly fever can be transmitted by the *Stegomyia* mosquito.

If each disease is capable of being conveyed only by one insect a real distinction between dengue and sandfly fever will be established.

SPECIAL ARTICLE.

"PROCEEDINGS OF THE INTERNATIONAL CONFERENCE ON HEALTH PROBLEMS IN TROPICAL AMERICA."*

MANY of the larger industrial concerns in world industry have learnt the lesson that "health is wealth," and pioneer among them in the tropics, perhaps, stands the United Fruit Company with its splendid and beneficial record of public health work in tropical America. The conference at Kingston, Jamaica, from July 22nd to August 1st, 1924, was held at the instance of the company and was attended by some 88 delegates, whilst 71 papers were read. Among the English delegates were Dr. Castellani, Sir James Kingston, Fowler, Dr. Arthur Horn, Sir Arbuthnot Lane, Sir Arthur Newsholme, Sir Leonard Rogers, Dr. J. W. Stephens, Dr. J. G. Thomson; Canada sent Dr. Banting; and Germany, Professors Fülleborn and Mühlens; whilst almost every distinguished research worker in the field of tropical medicine in America was present. We do not know whether this wonderful volume of the proceedings is on sale, but many medical research workers in India have received free copies with much appreciation. A conference on the problems of tropical medicine, attended by 88 of the leading medical research

* Proceedings of the International Conference on Health Problems in Tropical America, held at Kingston, Jamaica, 1924. Published by the United Fruit Company, Boston, Massachusetts, 1924, pp. 1010.

workers in the world, lasting eleven days, and at which 71 papers were read was bound to be productive of results. We have no hesitation in saying that this wonderful book is one of the most important contributions ever made to tropical medicine; from cover to cover it is of absorbing interest; almost every paper in it is worthy of abstract and review; whilst the fully recorded discussions are exceedingly valuable. Despite the pressure upon our available space, the great importance of this volume merits a full review.

Tropical Hygiene.—In the opening address Dr. W. E. Deeks spoke of the world-wide warfare against tropical diseases, and was followed by Dr. G. E. Vincent, president of the Rockefeller Foundation, on tropical hygiene as an international adventure. What is the future of the tropics to be? he enquires. The wonderful results of Gorgas in the Panama Canal zone would suggest the possibility of the successful colonisation of tropical countries by white races; yet many authorities consider that this will never be possible, for climatic reasons. A third theory looks forward to a future when the indigenous races will rule themselves, will protect health, encourage education, exploit natural resources, organise industry and commerce and take their places as independent but co-ordinate units in a world system of reciprocal service and co-operation. But, whatever the future, one fact holds good; progress in industry or wealth is absolutely dependent upon progress in public health methods and in the study of tropical medicine. Schools of tropical medicine are becoming more and more numerous throughout the world; in over 450 medical schools to-day investigative work on tropical medicine is being carried on; whilst at least 40 medical journals deal specifically with diseases of the tropics. The establishment of the Health Section of the League of Nations is the most notable step which has ever been taken towards a truly international organisation of public hygiene; all over the tropics large commercial industries are beginning to subsidise health campaigns; whilst the Rockefeller Foundation covers the globe with its network of beneficial activities. The day of the early pioneers ceased some thirty years ago; since then tropical medicine has become an international adventure, and one of ever more and more importance. Yet we are only at its beginning; the future should see the human race organised to fight disease in a manner which has never before been possible.

Dr. J. L. Todd, from McGill University, followed with an address on "Tropical Medicine, 1898 to 1924," an essay which should be read by every medical man in the tropics. In 1898 Ross worked out the mosquito cycle of the malarial parasite, Grassi confirmed and completed his work, "and then the flood gates opened." From then till now scarcely a month has passed without a report of some new important advance in knowledge concerning tropical diseases. The day of the pioneers is over; "it has come to be recognised that the best method of tackling a research problem is to collect together a group of investigators, each with special capacities for dealing with some aspect of the problem, equip them with every facility for their work, place them in contact with their problem, and then leave them alone." That was how the sleeping sickness transmission problem was solved; it will probably be the way in which the kala-azar transmission problem will be solved. Further, in tropical medicine, the use of the microscope and of laboratory methods becomes daily of more and more importance. Many doctors return from the tropics to England to wonder at the unprogressive state of medicine in temperate climates; to ask why the profession at Home have never yet succeeded in finding the ætiological micro-organism of the common cold, or a cure for this universal malady. Actually tropical medicine is to-day probably in a more flourishing state than medicine in the temperate zones. Yet the "time-size" of the world is rapidly altering with increasingly speedy modes of transit; the tropics are the world's sources of food and raw material for

industries, and tropical hygiene is perhaps the most important problem of the future.

Dr. M. J. Rosenau dealt with the seasonal prevalence of disease. Measles, influenza, and other infectious diseases, even infantile paralysis, shew definite cyclical variations in prevalence. Why? The question has not yet been answered, but a consideration of the problem shews how many factors are concerned; the seed, i.e., the prevalence and virulence of the infecting organism; the soil, i.e., the degree of resistance of the population at risk; and the environment. Measles, a mild disease in temperate countries which have long been used to it, may assume virulent characters in a virgin soil. In insect-borne diseases, of course, seasonal variation is marked, and depends upon the seasonal prevalence of the insect concerned; intestinal affections tend to depend upon temperature and humidity factors; crowding, as in the cold weather, is an important factor in respiratory diseases. The seeding of communities with a virus is an important element in the epidemic and endemic prevalence of diseases. In a well-seeded community where equilibrium has been reached, the introduction of susceptible persons will cause an epidemic recurrence both among themselves and among the old residents. The study of epizootics under laboratory conditions is a new angle of approach in the study of epidemiology and should throw much light on the causes of seasonal prevalence.

Malaria.—Dr. C. C. Bass discussed the relation of malaria carriers to malarial incidence, and Dr. W. M. James the localisation of malarial parasites in the body, combating the view that in malignant tertian malaria there is blocking and stasis of the capillaries of the internal viscera; on the contrary there is cerebral congestion and even hæmorrhage, but little evidence of stasis. In the discussion which followed, Dr. H. C. Clark gave the following interesting findings in connection with malaria in pregnancy:—

Positive mother's peripheral blood:	
thin films	12.9 per cent.
Positive mother's peripheral blood:	
thick films	22.5 per cent.
Positive placental blood films	48.3 per cent.

and pointed out how, in malaria, parasites tended to accumulate in the larger blood spaces and sinuses, rather than to block the finer capillaries. The rib marrow is a site where parasites may often be discovered at a postmortem, when they cannot be found in films from the other viscera. Dr. Castellani drew attention to malarial appendicitis, and Dr. Fülleborn to the prevalence of afebrile malaria carriers; thus Mühlens had found one-third of the school-children in the villages near Hamburg infected, yet without symptoms. Sir Leonard Rogers drew attention to the pioneer work of Ross and Christophers on the connection between malaria and rainfall, to Colonel Gill's well-known work in the Punjab and the great value of his malarial forecasts year by year. Several speakers insisted that quinine is still the best cure for malaria and the best drug for eradicating carriers, but that its administration must be supervised. Dr. J. G. Thomson spoke of the entirely different distribution of species of malarial parasites in different countries; thus in Rhodesia he found that 96 per cent. of infections were with *Plasmodium falciparum*, but, whilst blood films from infected children shewed numerous crescents, films from adults shewed ring forms but no crescents. Professor J. W. Stephens raised several questions; are malarial parasites ever extracellular? how does the infection pass across the placenta from mother to foetus, as it has now frequently been proved to do? why is early and primary malaria, utilised as a treatment for general paralysis of the insane, so easy to cure with quinine, whereas old-established and relapsing malaria is so difficult to eradicate? what is the relationship of the parasite itself to "malarial" dysentery, appendicitis and the like? Dr. F. L. Hoffman recorded how he had traversed the intensely malarious tract from the Andes

to the Atlantic shore of South America, fortified by 5 grains of quinine each morning and evening, without contracting malaria. Dr. Greenwood, of the Standard Oil Company of Venezuela, spoke of his introduction of Major Sinton's formula for quinine administration in that country. In summarising the discussion, Dr. Bass said that he had been searching for seven years for a case of malaria which had failed to respond to 30 grains of quinine a day, taken in solution by the patient under supervision (and not merely prescribed by the doctor), and had not found such a case; but it takes eight weeks to reduce the relapse rate to 5 to 10 per cent. Dr. W. M. James drew attention to the necessity for the definition of the term "cure"; was the relief of symptoms meant,—a relatively easy problem; or the eradication of infection in the patient,—a relatively difficult problem? In sections of infected tissue he had found but little evidence of an extracellular location of malarial parasites; whilst he believed that congenital transmission of malaria from mother to foetus only took place by accidental ruptures of the placenta; sections through the placenta of an infected mother will shew myriads of parasites on the maternal side, but none on the foetal side.

Dr. N. P. Macphail, in a paper on modes of administration of quinine in malaria, claimed that for oral administration the more insoluble salts give as good results as the more soluble ones; that quinine gives as satisfactory results when administered twice a day as when given three times a day; that "the intramuscular injection of quinine is an efficient and practical method of quinine administration. The danger of tissue necrosis incidental to the intramuscular injection of quinine is small and insignificant when we take into account its life-saving property." In the discussion which followed Dr. C. C. Bass, whilst agreeing with him with regard to the salts for oral use, disagreed with regard to intramuscular quinine; "the large number of abscesses and the damage to the tissue that occurs in a large percentage of the cases when the injections are made by many different doctors and nurses, is very impressive. It certainly has been quite impressive to me.....It is quite a formidable procedure,..... before using this method, the doctor should take a few injections himself." (The reviewer, after an involuntary personal experience of intramuscular cinchonine bishydrochloride in malaria, entirely agrees with Dr. Bass. There are few procedures more painful.) Dr. R. C. Connor, Ancon, Canal Zone remarked that intravenous quinine was safe if the doctor who gave it had been instructed in the necessary technique. Colonel J. Cran spoke of a 20 years' personal experience of intramuscular quinine and was a warm advocate of the method for critical and severe cases. Dr. W. M. James spoke of the numerous parties who disappear into the malarial hotbeds of South America with no accompanying doctor, armed only with insoluble quinine pills, the members of which return to Panama within a few days "ready for the cemetery." His own experience was that abscesses occurred in about 0.5 per cent. of intramuscular injections of quinine.

Drs. M. A. Barber and W. H. W. Komp then read a paper dealing with an exceedingly ingenious method of simultaneously taking thin and thick blood films in malarial survey work. From each child examined a thin film and a thick film are taken simultaneously on the two halves of the same slide. These are marked with a number and dropped, one by one, into the usual pattern of slide box. Strips of cardboard of suitable thickness are now inserted between each two slides, and the box inverted when the films have dried. On removal of the inverted cover of the box, the slides plus cardboards are bound into a bundle with a strong rubber band. They are now dipped thick film end downwards to half their length—whilst still held together by the rubber band—into a bath of Giemsa's stain; 1.25 c.c. to 75 c.c. of water; stained; gently washed; allowed to dry, and examined. As a rule only the thick film is examined; but if necessary, the thin

film on the other half of the slide can be stained and examined subsequently. Dust must be avoided in the technique and a good brand of stain is essential. Dr. H. C. Clark spoke of having tried this technique in 1,431 cases; the Barber thick film technique gave 46 per cent. of positive findings; whereas thin films from the same patients taken at the same time gave only 17.5 per cent. of positives. The chief disadvantage of the thick film method, however, was the difficulty of recognising young ring forms; whilst, actually, owing to the great prevalence of malaria in certain localities, the discovery of a malarial infection in a patient by the thick film method might lead to treatment of the malaria and overlooking of the primary disease concerned.

Dr. F. M. Johns spoke of the results of an extensive investigation into thick film methods in connection with the Rockefeller Foundation anti-malarial campaigns. He advocated taking a thick and a thin film upon the same slide, using less than one drop of blood for the former, dehaemoglobinising with acetic acid alcohol, and staining with polychrome methylene blue, followed by eosin. The discussion clearly shewed that, whilst many workers are strongly in favour of the thick film method, there is as yet no unanimity as to the best technique.

Blackwater Fever.—Papers on blackwater fever and haemoglobinuria followed next. Dr. J. W. Stephens first gave a concise and very admirable exposition of our present knowledge of the disease,—a paper which summarises to some extent his admirable series of recent publications on the same subject in the *Annals of Tropical Medicine and Parasitology* of recent years. Dr. J. G. Thomson followed with an account of the morphology of *P. falciparum*, as found in association with blackwater fever in his recent enquiry in Rhodesia, the results of which were reported in the same journal. He believes:—(1) that blackwater fever is always associated with the malignant tertian parasite, the instances of association with the benign tertian and quartan parasites being in all probability, merely instances of mixed infections. (2) The geographical distribution of blackwater fever depends upon the geographical distribution of the three (or more) different species of malarial parasites; it is a disease of countries where *P. falciparum* predominates, as in Rhodesia where over 96 per cent. of the infections are with this species. (3) The virulence, and to some extent, the morphology of this species of malarial parasite appears to vary from time to time and from one area to another, and in some instances we get relatively large ring forms, 2.5 μ or so in diameter, together with marked stippling and degeneration of the infected red corpuscle. (4) It is apparently this altered chemical reaction of the red cells which is responsible for the production of blackwater fever by this parasite. These altered cells appear to act as foreign bodies capable of producing a haemolytic amoebocyte, and this haemolytic substance will act only on cells so altered. Pernicious stippling and altered staining reaction of the corpuscles are the chief features associated with blackwater fever; where such findings are present in an area, there blackwater fever exists; where they are absent, it does not. The morphology of malignant tertian malarial infection appears to be different, for example, in England and Rhodesia; but whether this is evidence of the existence of two different species of malignant tertian parasite must be left an open question.

There followed, as might have been expected, an exceedingly interesting discussion. Dr. W. M. James hoped that the solution of the blackwater fever problem would ultimately be found in the laboratory; at least the clinician appeared to be incapable of solving it. In the Panama Canal zone they had found the closest relationship between malaria and blackwater fever. The labouring negro population took no advantage of the screened huts provided, but they were more or less immune to malaria, and shewed but little malaria and little blackwater fever. The American staff took the

fullest advantage of screening against mosquitoes, and also had but little malaria and little blackwater fever, but from causes different to those in connection with the negro population. The "poor whites," labourers, etc., from the countries in Southern Europe were non-immunes, took but little trouble in anti-malarial measures, and were heavily affected with malaria and shewed the chief incidence of blackwater fever. Further, the incidence of blackwater fever corresponded to rainfall, and the local Panamanians were nearly immune. Some 80 per cent. of blackwater fever cases shewed the presence of *P. falciparum*, and when the medical history sheets of such as shewed *P. vivax* came to be examined, it was frequently found that they had previously shewn *P. falciparum* also. He agreed entirely with Dr. Thomson that blackwater fever was a manifestation of malignant tertian malaria, under certain circumstances. His treatment for the disease was prayer; there was nothing more difficult; cases with and without quinine did equally well or equally badly; finally the clinician must be on the lookout for malarial cases with temperature charts suggestive of a plateau, often with a continued fever resembling that of typhoid fever. Dr. C. C. Bass thought that, whilst the best treatment of blackwater fever might be prayer, its best method of prophylaxis was prophylactic quinine for the susceptible individual. Dr. Castellani considered that the term blackwater fever covered three entirely different conditions:—(1) A manifestation of malignant tertian malaria under certain circumstances; (2) quinine hæmoglobinuria, and (3) a small residuum of some 2 to 3 per cent. of cases which might be an entirely different type of disease having no connection with malaria; "as a general rule, however, blackwater fever is malaria." Dr. R. R. Nutter believed that prophylactic quinine as usually administered was often insufficient to prevent malaria, but an important ætiological agent in the production of blackwater fever. Dr. H. C. Clark spoke of the postmortem findings in 66 cases in the Canal zone. The incidence was chiefly in males, and the greatest age incidence at 20 to 40 years of age. Cases occurred chiefly among Spanish immigrants who had resided from 1 to 7 years in the Canal area. He was "reasonably sure that blackwater fever is a sequel of æstive-autumnal malaria due to *P. falciparum*. Professor Stephens, in closing the discussion, said how disappointed he was in the extraordinary unanimity of opinion shewn; he had expected a variety of views as to the causation of blackwater fever; whereas the discussion had shewn a complete unanimity in accepting its malarial origin.

Dr. F. M. Root then read a paper on American anophelines, and Dr. J. A. Le Prince one on Anopheles control. In the latter are some very interesting figures. In the U. S. A. the public pay the manufacturers of metal screening against mosquitoes some 25 million dollars a year; but, owing to defective screening often fail to get value for their money. In Panama mosquito traps had proved a success; so also had providing special anopheline breeding places which could be used as bait for mosquitoes, and then drastically dealt with. Top minnows and other suitable fish were not used nearly as much as they should be. The bionomics of Anopheles mosquitoes required further study. Paris green, used as a cloud spray, was one of the most effective and cheapest remedies for breeding places. Instances were quoted where engineers had given extravagant quotations for the cost of anti-malarial measures, but where the medical men on the spot had been able to devise effective measures at one-twentieth to one-fortieth of the cost. In brief, mosquito control could be so cheapened by the devising of suitable measures for different areas as to become a practicable proposition even for a poverty-stricken country. Dr. H. R. Carter enlarged upon the same theme. It had cost about \$1.05 per head to rid an area in North Carolina of malaria, but the business organisations concerned estimated that this expenditure had been saved ten times over in the improved public health.

Municipalities might be slow in learning the lesson that anti-malarial measures pay, but he had found that business organisations were not; they were becoming increasingly interested in public health measures as a paying proposition. Dr. Seale Harris spoke of one company which had reduced the incidence of malaria among its employees from 2,000 cases a year among a population of 100,000 to less than 150 cases a year. The Rockefeller Foundation's anti-hookworm campaign in the Southern U. S. A. had awakened the states concerned; to-day they placed public health measures in the forefront of their programme.

Yellow Fever.—A series of papers on yellow fever by Dr. H. Noguchi and his colleagues followed next, and revealed a wide divergence of opinion in the discussion which followed. In Brazil Dr. Noguchi and his co-workers have isolated *L. icteroides* in 2 out of 9 cases of yellow fever, the virus producing typical symptoms in inoculated guinea-pigs, monkeys and dogs. Sera from convalescent Brazil patients gave typical positive Pfeiffer reactions with strains of the same organism as isolated from cases in Peru, Ecuador, and Mexico. An amount as small as 0.0001 c.c. of an immune serum from horses protected guinea-pigs against 1,000 minimum lethal doses of infected guinea-pig kidney. Dr. H. R. Muller contributed a detailed account of the histopathology and hæmatology of experimental yellow fever in animals shewing how parallel are the findings to those of yellow fever in man. Lieutenant-Colonel J. Cran, R.A.M.C., dealt with the results of the use of Noguchi's serum and vaccine in an outbreak of yellow fever at Belize in British Honduras, where 17 cases occurred in a college. Every other inmate of the college was given the vaccine and the buildings were fumigated. Finally all inmates of the college were segregated on an island where there were no stegomyia, some 12 miles distant. Some 500 persons in the town were also vaccinated, and among these no case occurred. Three cases occurred in the town amongst those not vaccinated. The 17 cases were all treated with Noguchi's serum; of 13 which received the serum on the 1st or 2nd day, only 1 died; of 4 which received it on the 4th to the 6th day of illness, all died. The Rockefeller Foundation came to the rescue and carried out a most vigorous anti-mosquito campaign. Within a few months the mosquito index had fallen from 50 per cent. to within the 5 per cent. index which is regarded as the safety line, and has remained at the lower figure since.

Dr. A. Agramonte drew attention to the rôle of children in maintaining endemic conditions; he trusted that, with the introduction of Noguchi's vaccine, sanitary officers would not neglect other and more useful measures. *L. icteroides* was a most interesting organism, but he doubted its specificity and its causative rôle in yellow fever. One of the most curious features of yellow fever was its spontaneous tendency to apparently die out, only to reappear again in the endemic areas. The quarantine regulations were most essential in the campaign against the disease. In reply, Dr. Noguchi referred to the failure of Lebrado and Hoffman in Havana to isolate *L. icteroides*. Their guinea-pigs had shewn leucocytosis and probably a secondary infection had occurred; whereas in his own experimental animals the symptoms were typical of yellow fever. Morphologically *L. icteroides* is thinner and shorter than *L. icterohæmorrhagic*, whilst the serological reactions of the organisms are quite different. Dr. H. R. Carter said that the difference in symptoms between guinea-pigs inoculated with *L. icteroides* and *L. icterohæmorrhagic* differed in degree, but not in kind. Earlier brews of vaccine had contained agar and caused severe abscesses. To estimate the value of a vaccine the data must be comparable. "It is all very well to vaccinate a man, and then have him develop no yellow fever. But unless groups of vaccination you can get two groups of men, one unvaccinated, and both groups equally exposed to yellow fever, you cannot judge of the efficacy of

vaccination." The evidence was suggestive of the value of the vaccine, but did not provide proof. Dr. Noguchi then gave further figures collected from different districts: in Mexico in September to December 1920, 19 cases treated with serum with 3 deaths as against 57 deaths in 106 untreated cases; in Tuxpan a severe outbreak occurred between August and December 1920, with 86 cases; 2,000 persons were vaccinated between October 7th and November 5th and 16 of them contracted the disease, but in every instance the patient was incubating the disease when vaccinated. Major H. J. Nichols accepted *L. icteroides*; in fact he considered that the organism was first seen by Stimson in 1905 in sections of the kidney of a case and named by him *S. interrogans*. Lieutenant-Colonel J. Cran said that when he compared the 1921 epidemic in Belize with the 1905 one the difference reminded him of the difference in the treatment of diphtheria before and after the use of antitoxin.

After a paper by Dr. R. H. Carter, on preferential and compulsory breeding places of *Aedes (Stegomyia) ægypti*, Professor Fülleborn read an exceedingly interesting paper on the blinding filaria of Guatemala, (*Onchocerca cecutiens* Brumpt, 1919). Dr. F. G. Rose recorded the treatment of filariasis by Bayer 205: it was found to cause a sharp initial rise in the number of microfilariae, followed by a pronounced fall, which, however, is only of a temporary character, though it may be noted from time to time for 2 or 3 months.

Amœbiasis.—Drs. W. M. James and W. E. Deeks next contributed an admirable paper on the ætiology, symptomatology and treatment of intestinal amœbiasis. In 1914 these workers were the second to establish clearly the difference between *E. coli*, as a harmless commensal living in the colon, and *E. histolytica* as the parasite of amœbic dysentery, thus confirming the work of Walker, 1911 at Manila. Their view that *E. histolytica* is normally a parasite of the lumen of the gut and only pathogenic when it takes on tissue-invading powers is novel, and completely at variance with Dobell's view that in the carrier state the entamœbæ live in the mucous membrane of the colon and in nests in the sub-mucous tissue. Intestinal amœbiasis is protean in its symptomatology and acute and sub-acute dysentery are not its most common manifestations. The small strains of *E. histolytica* are most important and their small "minuta" cysts those most often missed in laboratory examinations. The use of human faeces as garden manure is an important factor in the spread of endemic amœbic dysentery in the Canal zone. Turning to symptomatology, latent infections are found most frequently in children. In adults reflex digestive disturbances are common, and the cæcum and appendix are frequently infected; often, on deep palpation, localised and fixed points of tenderness may be elicited in the colon. Colicky pains, with or without constipation—most frequently with alternating constipation and diarrhoea—are common. Appendicitis, cholelithiasis, renal colic and even diverticulitis may be simulated by an amœbic infection; mild cases are often mis-diagnosed as "mucous colitis," and in many such cases repeated examination of the stools may be required before the entamœbæ are found. Repeated and severe hæmorrhages from a small lesion may lead to a mistaken diagnosis of malignant growth in the colon. A severe type of local invasion may almost completely block the lumen of the colon, and palpable masses resembling tumours may result.

The standard treatment adopted by the authors for amœbic dysentery is as follows:—(1) Absolute rest in bed. (2) A generous milk diet, which will leave practically no residue in the colon. (3) Saline or warm water irrigations one to three times a day as lavage. (4) Bismuth subnitrate, a heaped teaspoonful, or about 180 grs. every three hours, suspended in a tumblerful of water,—lessening the amount only when improvement takes place. In very chronic cases, bismuth administration may have to be continued for 2 or 3 months after convalescence is established. The suspension in

water is necessary to prevent the bismuth from forming a paste or solid mass. Resumption to a normal diet must be gradual and be as carefully controlled as with a typhoid patient. (5) Emetine hydrochloride, $\frac{1}{2}$ to 3 grains a day hypodermically or orally until the limit of tolerance is reached. Under this régime, the case mortality at Ancon Hospital has fallen from 6.2 per cent. in 1914 to 1.7 per cent. in 1923. In 66 cases observed for some months after the conclusion of treatment, relapses occurred in only $4\frac{1}{2}$ per cent. Finally, the treatment is essentially a hospital one, and only suitable for in-patients under full control.

Drs. C. Garin and P. R. Lépine commented on the increase of amœbic dysentery in France among the civilian population since the war, owing to the introduction of infection by colonial troops. Relapses are common, anæmia is often marked, whilst the suprarenal glands are often affected, and the adrenalin content low. Different new remedies were tested. (1) A standard treatment for amœbic dysentery, of 50 cgms. stovarsol daily, for the 1st and 3rd weeks; supplemented by emetine during the 2nd and 4th weeks, and finally followed up by 25 cgms. of stovarsol daily for a further 1 or 2 months. No *E. histolytica* were found in the stools after the 8th day, whilst infections with *Giardia* also disappeared, but not those with *Trichomonas*. (2) Acetylarsan, a white crystalline powder, readily soluble in water, was also found to be of value in amœbiasis: 6 or 7 doses, each of 75 cgms. in solution are given at 3 to 8 day intervals. Entamœbæ disappeared slowly after the 8th day, but *Giardia* infections were at once cleared. Both drugs appear to be but very little toxic.

In the discussion following these papers Sir Leonard Rogers said that in the severe amœbic dysentery of the tropics the rule should be emetine first and arsenical preparations second. Dr. R. C. Connor said that there were very few laboratory men really competent to diagnose cysts of *E. histolytica*. He rarely exceeded 9 grains in any course of emetine injections and preferred intermittent courses of injections to overdosing the patient with emetine. Sir Arbuthnot Lane spoke of chronic dysentery cases which had returned to England and whose symptoms had cleared up after operation and division of "the first and last kink" and cure of their intestinal stasis. Dr. Fülleborn drew attention to the difficulty of sterilising fresh vegetables and green stuff in the tropics. Dr. Agramonte spoke of the reduction in dysentery mortality in Cuba following a vigorous conservancy campaign. Dr. Kofoid spoke of constipation as a symptom of intestinal amœbiasis, and described his laboratory technique in examination for cysts. Sometimes as many as 30 and 40 negative examinations had been followed by a positive. In one case continuously observed for 46 days the number of cysts passed per day varied from nil to over 800 million. Aerial dust, rather than water-supplies, was the mode of transmission of the cysts. Americans returned from tours in the tropics shewed more than double the carrier incidence shewn by those who had stayed at home. Dr. Nichols referred to Boeck's recent successful cultivation of *E. histolytica* in vitro. The part that Vedder had played in the introduction of emetine should receive recognition. One grain of emetine a day for 10 days was enough to make a person feel as if he had locomotor ataxia; the administration of the drug must be controlled and watched. Dr. S. Harris spoke of the value of infusions of green vegetables in treatment. Colonel Ashford described a case of pleural effusion due to *E. histolytica*, following upon an old liver and lung abscess which had occurred years before: the exudate on the pleura was "a mass of amœbæ." Dr. A. R. Paterson spoke of the dangers of bismuth poisoning by absorption through an ulcerated gut. Dr. Ureta advocated 3 to 5 grains of ipecac in a gelatine capsule at bedtime for discharged cases. Dr. A. A. Facio had seen a case of peripheral neuritis follow large doses of bismuth; the blood picture was very much like that in lead poisoning. Professor Mühlens

said that at Hamburg they had been driven to yatren in preference to all other treatments: dose 1 gram or 15 grains 3 to 4 times daily for one week, by the mouth; or a daily enema of 200 c.c. of a 2 per cent. solution. The patient must be taught to retain the fluid as long as possible. The results were admirable, especially in emetine-resistant cases.

Drs. R. W. Runyan and A. B. Herrick then read a paper on the surgery of amœbiasis. In two instances they record what is apparently true amœbic abscess of the appendix. The appendix was often a resting nidus for entamœbæ which had survived the emetine treatment, and which re-invaded the colon; appendicectomy might cure a chronic amœbiasis. In 4 cases chronic amœbic infection of the cæcum had led to the formation of large tumour-like masses with almost complete blocking of the lumen of the gut. In 3 of these recovery followed after operation. Cæcostomy was to-day but rarely necessary, even in severe cases. For liver abscess they advocate open incision and drainage,—(a recommendation with which we think that few medical men in India to-day will agree). Abscess of the brain is usually very rapidly fatal. In the pre-emetine days they had seen cases of cæcostomy followed by destruction of large areas of the abdominal wall by *E. histolytica*.

Sir Leonard Rogers followed, with a paper on amœbic hepatitis. During the last two decades, he claimed, our advance in knowledge of this subject has surpassed that in almost any other branch of tropical medicine. He described how he had shewn the close relationship between liver abscess and amœbic dysentery, had demonstrated the living amœbæ in the walls of liver abscess cavities, and had re-introduced the ipecac treatment which had been used by McLean, Norman Cheevers and the early pioneers, but which had then gone out of fashion, and been replaced by ammonium chloride with disastrous results. The operative mortality in those days of open operation for liver abscess varied from 50 to 60 per cent. in British station hospitals to 70 per cent. in civil hospitals. Work followed on the leucocytosis in amœbic hepatitis, and the recognition of the pre-suppurative phase. Turning to the rational present-day treatment of amœbic hepatitis, the emetine treatment must be begun before surgical intervention and carried on until the amœbæ are all killed. The following are some of the figures quoted which shew the enormous improvements effected by Sir Leonard Rogers' work:—

- (a) Rogers, Lettsomian lectures, 1921. Records of 2,661 cases treated by open operation in pre-emetine days. Mortality 56.8 per cent.
- (b) *Ibidem*. 111 cases—mostly advanced ones—treated by aspiration with trocar and cannula plus emetine. Mortality 14.4 per cent.
- (c) K. K. Chatterji. 186 cases treated by aspiration, irrigation plus emetine. Mortality 1.6 per cent.
- (d) The mortality in the British army per 100,000 from liver abscess in 1898 to 1907 was 139; in 1908 to 1912 was 51; in 1913 to 1920, after the introduction of emetine, was 19. Only one case of liver abscess in 29 cases of dysentery occurred in 1912 to 1919 as against a proportion of 1 to 8 in 1908 to 1911.

Dr. J. J. Valarino then read a paper, illustrated by admirable photographs, on the value of x-rays in estimating the extent of amœbic ulceration of the colon. The value of the opaque meal and radiographic study in cases of chronic amœbic ulceration is very great. The parts affected in order of frequency were the cæcum, ascending colon, hepatic flexure and sigmoid colon. Dr. H. C. Clark gave an account of the amœbic lesions and complications found in 186 postmortem examinations between 1905 and 1923. In 55 instances the entire colon was involved, in 48 the entire colon and appendix, in 24 the cæcum and ascending colon. Taking cases with only early ulceration, the primary seats of election appeared to be in order of frequency the cæcum, the ascending colon, rectum, sigmoid and appendix. The

transverse colon was least affected; 76 cases shewed amœbic ulcerative appendicitis, resulting in 9 per cent. of cases in abscess or perforation. 95 of the cases shewed liver abscess. Rather unexpectedly 55 of these were multiple as against 40 cases with solitary abscess. A tribute to emetine therapy was the fact that the number of cases of amœbiasis per 1,000 postmortems had dropped from 61 in 1907-1910 to 3 in 1920-1923.

A paper by Drs. Kosoid, Boyers and Swezy followed dealing with systemic infections by *E. histolytica*. The entamœbæ, as is well known, tend to spread into the capillaries and veins of the colon submucosa, and so to be swept to the liver and brain, where they lodge and cause tissue necrosis with abscess formation. But, though this may be the usual sequence of events, they may also lodge in other organs, and they have been found by the authors in the bone marrow in a case of arthritis and in the lymph glands in cases of Hodgkin's disease. (The authors' criteria that the forms seen were entamœbæ and not tissue cells are that they shewed persistence of the nuclear membrane in karyokinesis and 6 chromosomes, with 12 in mitosis,—characters foreign to any tissue cell of man. Motile amœbæ were apparently not observed). The parasites apparently have a special affinity for mesenchyme and connective tissue regions. This amœbic septicæmia may lead to most unexpected sequelæ: rheumatism, chronic invalidism in middle age, iritis, etc., whilst entamœbæ have also been found in the testis, semen, spleen and in skin ulcers. The routine examination of patients' stools for cysts is hence a most valuable measure.

Intestinal Flagellate Protozoa.—Dr. R. W. Hegner gave an interesting account of experiments on the control of intestinal protozoal infections in rats by change of diet. No ciliate infections have ever been reported in carnivorous animals, whereas they are very common in ruminants; flagellate intestinal protozoa are also rare in carnivora. In rats parasitized with intestinal flagellates it was found that a change to a purely carnivorous diet eradicated or greatly reduced these infections. In one patient with diarrhoea and a *Trichomonas* infection, both the diarrhoea and the flagellates disappeared entirely after 3 days' treatment, and all findings were negative for the next 32 days. In the discussion which followed, Dr. Kosoid drew attention to the pathogenicity of *Pentatrichomonas* as compared with other species of *Trichomonas*, and to the fact that rats could be cleared of their natural intestinal protozoal infections for experimental purposes by feeding them with bread soaked in Epsom salt solution. Dr. Seale Harris sounded a note of warning with regard to feeding patients on a purely carnivorous diet; it would only be possible to carry this on for a few days. Dr. W. E. Deeks considered that there was not sufficient evidence to incriminate the intestinal flagellates as pathogenic; correct the diet and the patient with diarrhoea gets well but may still shew a flagellate infection. His routine treatment was 15 minims of dilute nitric acid with $\frac{1}{2}$ a drachm of essence of pepsin before meals.

Bacillary Dysentery.—Drs. R. C. Connor and L. B. Bates then read a paper on bacillary dysentery as observed at Ancon Hospital during the past five years. The spread of this disease they believed to be wholly due to carriers; the water and milk supplies and conservancy methods were irreproachable. On routine plating of stools from all cases of enteritis from 1918 to 1923, 66 cases of bacillary dysentery had been discovered, the age incidence ranging from 3 months to 59 years. Most of these occurred in October, November and December, and 19 died. Of the infecting strains 39 were of Flexner-Y type, 4 of Shiga type, 18 of the Sonne type, and 5 of undetermined type. Children are especially susceptible to bacillary dysentery, and the disease is very fatal among them. Ten per cent. of cases were not diagnosed during life, but only at post-mortem. The carrier state might persist up to at least the 4th month of convalescence after bacillary dysentery. Treatment of the disease was symptomatic. In

hospitals special care should be taken to prevent the spread of the disease to other patients. "Many physicians in the tropics do not seem to be aware of the frequency and seriousness of bacillary dysentery, especially in infants and children."

Dr. W. H. Park mentioned that sometimes the Flexner type of bacillus could cause epidemics with quite severe symptoms. Dr. Castellani described the characters of the Sonne bacillus, *B. metadysentericus*, which produces acidity but no gas in lactose when recently isolated; also of his *Vibriothric zeylanica*, with colonies identical with those of the dysentery bacilli on MacConkey's medium. For children he advocated the rhubarb treatment:—pulv. rhei. co. 1 to 2 ozs. in 2 ozs. of chloroform water; shake the bottle and give one teaspoonful every 2 hours to a child 2 years of age. The dysentery quickly clears up. Unfortunately this treatment is not so successful in adults. Dr. H. J. Nichols considered bacillary dysentery to be the most important military medical problem in the Philippines. Cyto-diagnosis was the most rapid method of diagnosis. Dr. W. H. Park commented on the manufacturer's habit of labelling a serum "polyvalent" without stating what strains it is potent for. Serum should be kept on ice. Dr. P. W. Wilson drew attention to an outbreak in Haiti, from which carrier emigrants might carry the infection to other countries. In summing up the discussion, Dr. Connor remarked "what we are trying to do is to get the doctor to think in terms of bacillary dysentery whenever he has to deal with a gastro-intestinal upset, especially in children."

Inguinal Granuloma.—Dr. J. Iturbe then read a paper on *Schistosoma mansoni* infection in Caracas, describing its life history and its transmitting snail host of genus *Limnæa*. Dr. F. M. Johns followed with a paper on inguinal granuloma, claiming it to be due to Donovan's organism: this is an organism of Chlamydozoal type, plump, rounded and glistening in fresh preparations; staining badly; so far not cultivated with success; and found in intracellular masses in the endothelial cells of the granuloma. Treatment with tartar emetic, 5 to 12 c.c. intravenously of a 1 per cent. solution at 2 to 3 day intervals until the lesion has healed,—was said to be strikingly successful. After the 5th or 6th dose the "Donovan bodies"—(which are quite different from *Leishmania donovani*)—disappear. Complete healing of the lesion however, may take from 1 to 3 months. Interrupted courses of treatment might prove better than one long continued one. All attempts to transmit the disease to animals had failed. Dr. J. G. Thomson pointed out that the constant finding of an organism associated with a pathological condition did not prove that it was the cause of the disease; thus harmless spirochetes are very common in granulomatous lesions. Dr. Noguchi had found a minute spirochete, *Treponema genitalis*—in many similar lesions, but had failed to produce lesions with cultures of it in animals. Dr. C. C. Bass drew attention to the great prevalence of inguinal granuloma in hospital cases, and Dr. R. W. Runyan to the frequency of mixed venereal lesions,—chancroid often being complicated by syphilis.

Leishmaniasis.—A very important paper on certain biological aspects of Leishmania, by Dr. H. Noguchi followed—one which should be read in the original by all workers upon Leishmania infections in India. He first described his medium for the cultivation of Leishmania:—

0.9 per cent. saline ..	80 parts.
Fresh rabbit serum ..	10 parts.
2 per cent. nutrient agar, pH 7.2 ..	10 parts.

Rabbit hæmoglobin (made by taking 1 part of defibrinated blood with 3 parts of distilled water) 1 to 2 parts.

Upon this medium *Leishmania* grows luxuriantly in its flagellate form: the surface scum of 2 to 4 mm. thickness can be periodically skimmed off, and consists of herpetomonads: and the culture will remain viable

for several months. Rabbits had been immunised by repeated intravenous injection of massive doses of active cultures, and their sera used in the preparation of further media. It was here found that when the medium was prepared with heterologous serum, the cultures remained clear and translucent, but in homologous serum the cultures became granular in appearance from agglomeration of the flagellates. The serological reactions of the different strains establish three different species as valid, *L. donovani*, *L. tropica*, and *L. brasiliensis*, parasites respectively of the viscera, cutaneous tissues, and muco-cutaneous tissues. *L. infantum* gives the same serological reactions as *L. donovani*, and is presumably identical with it.

Turning to biochemical reactions, distilled water instantly plasmolyses *Leishmania*,—(which accounts for the fact that diluted Giemsa's stain is quite unsuitable for dehemoglobinising a thick film of blood from a suspected kala-azar case). The pH range of growth was from pH 5.08 to pH 7.21, but *L. tropica* grew even up to a pH of 8.8; *L. donovani* only up to a pH of 7.21. Saponin kills the flagellates at a 1 in 10,000 dilution. Cobra venom, activated by lecithin, killed at a 1 in 20,000 or even higher dilution. Tartar emetic kills the flagellates at a 1 in 100 dilution, but some flagellates survived at 1 in 1,000. As with the trypanocides so with tartar emetic, the drug appears not to become leishmanicidal until it is activated by union with the products of living tissue. Bismuth compounds proved very weak. The action of salvarsan and other arsenical derivatives was also investigated.

Finally, however, a drug was found with a very striking leishmanicidal action in neutroflavine, a derivative of acid acriflavine, (prepared by the National Aniline Co., 40 Rector St., New York City). At a 1 in 50,000 dilution this compound kills *Leishmania*: but if the mixture of flagellate culture and dye be exposed to a bright light, neutroflavine kills the flagellates at a 1 in 10,000,000 dilution,—a very striking photodynamic effect; and it is the short-length light waves and not the heat waves that bring about this effect. Further, the dye is almost completely devoid of toxicity for man, and after intravenous injection in the rabbit is still present in the circulating blood 2 hours after administration, but not at 20 hours. It is obvious, in conclusion, that we may have in this dye a drug of extreme value in the treatment of oriental sore, possibly also in the treatment of other *Leishmania* infections.

Finally, Dr. Noguchi had examined the *Leishmanias* of various Euphorbiæ plants in South America; also those of Hemiptera found feeding on infected plants. Morphologically these herpetomonads were found to be distinguishable from the herpetomonad forms of *Leishmania* of man. All attempts at culture had failed, and immunologically the serum reactions were quite distinct from those of the *Leishmanias* of man.

It will be seen that Dr. Noguchi's valuable paper constitutes a most important addition to the literature of the *Leishmania* problems. It was followed by a paper by Dr. Castellani advocating the treatment of oriental sore by phosphorus.

If the lesion is extensively ulcerated B. P. phosphorus oil is applied on a swab to the fundus and margins of the sore, at first every day, later at intervals of 2 to 3 days. If the nodule is not ulcerated, or only slightly so, in addition to the external application, 3 to 5 minims are injected into the nodule and into the skin around it once or twice a week. Seven cases had been treated with satisfactory results, and apparently complete cure in from 3 weeks to 3 months.

An interesting discussion followed. Dr. J. W. Stephens spoke of a case of oriental sore where a mistaken diagnosis of rodent ulcer had been made. The reports on the result of treating oriental sore by tartar emetic intravenously were very conflicting. Dr. H. R. Carter raised the possibility of there being two *Leishmania* infections in Brazil; espundia, indigenous to the country; and oriental sore, introduced into it from the Mediterranean. He had seen a large number of cases

of typical and often multiple oriental sore; and in some 40 to 50 per cent. of them espondia followed, and caused terrible deformity and even death.

Tropical Dermatology.—Dr. A. Castellani then introduced the subject of tropical dermatology. For axillary trichomycosis he advocated applications of 1 per cent. formalin to the armpits several times a day, with sulphur ointment used at night. The aetiology of mango toe was described; a good routine treatment consists of the application once or twice a day of 2 per cent. potassium permanganate lotion, followed by a boracic talc dusting powder. *Tinea flava* he differentiated from *tinea versicolor*, and reported ointment and turpentine as useful. igma was amendable to formalin applications. *Tinea imbricata* was a disease shewing no tendency to spontaneous cure and its treatment is very difficult: the best routine remedy was resorcin (1-2 dr.) dissolved in tinct. benzoninae co. (1 oz.) or chrysarobin ointment. A new type of blastomycosis cutis was described, clinically resembling acute furunculosis, but due to a yeast, and yielding only to massive doses of potassium iodide and autogenous vaccine. Pruritus ani is sometimes of mycotic origin, and this type shews no tendency to spontaneous cure: cautious applications of silver nitrate (grs. xv) in spir. aetheris nit. 1 dr.) were recommended. Dr. Connor drew attention to the relapsing character of dhotie's itch; the best preventative is the routine use of an alkaline dusting powder (sod. bicarb $\frac{1}{2}$ oz.: talc powder 8 ozs.) after the bath.

Drs. C. S. Butler, J. E. Houghton and G. F. Cooper contributed a paper on mycosis of the hands and feet. Such infections are world-wide. As the result of a questionnaire sent out to 500 officers and men of the U. S. Navy, 34 per cent. were found infected with fungi somewhere or another on the body, with an average duration of the lesions of 1.4 years. Methods of examining for, isolating and cultivating the different causative fungi were then described, and a full account of their morphology and cultural characters given. Treatment of these conditions, to be effective, must be continuous and prolonged; the resting and spore forms are deep in the epidermis, and until this has desquamated the infection will persist. Soap is useful, tincture of iodine for epidermophytosis of the pubes and axilla, and permanganate lotions where suppuration has occurred. Linimentum saponis is also very useful, used as a local application at night.

Dr. E. Urueta next read a paper on pinta, and Dr. A. A. Facio a very interesting one on ainhum, illustrated by skiagrams. The latter affection may affect other toes than the little toe, the chief radiographic finding is atrophy and disappearance of the middle phalanx, whilst sections of the diseased tissues shew marked sclerosits and partial obliteration of the arteries and marked infiltration with mast cells.

Tropical Surveys.—Professor Mühlens gave an account of a parasitological survey of some districts in the northern part of the Argentine. Examination of 7,024 persons' blood by the thick film method shewed malarial parasites present in no less than 2,331; all three species of parasite being fairly prevalent. Over 30 per cent. of the population are infected, in some schools up to 70 per cent., in some labour camps up to 100 per cent. Microfilariae abounded; in some regions 48 per cent. of the population are infected, the microfilariae are present in the peripheral blood both by day and night. The parasite is either *F. demarqui* or a new species, *F. lucumana*. Trypanosomiasis, on the other hand, was very rare, only 2 cases having been encountered. From one of these cases it proved possible to infect a mouse, although no trypanosomes could be found in thick blood-films. In the discussion which followed, Dr. Noguchi mentioned the possibility of cultural diagnosis of obscure cases of trypanosomiasis by using his leptospira culture medium.

Dr. A. E. Horn, delegate from the British Colonial Office, spoke on some aspects of tropical medical work.

Malaria was of course the biggest problem in medical matters in the Empire. Thus Mauritius, once a health resort, was now saturated with malaria: Fiji and Rodriguez islands had still escaped. And each district had its own problem: ill-considered or indiscriminate measures were useless: the local problem had to be studied. In Malaya in some places jungle-clearing in order to get rid of *A. umbrosus* resulted in providing breeding places for *A. maculans*, a still worse carrier. Temporary expedients might be utilised where funds were short. He described Fletcher's valuable work on different methods of quinine administration in malaria, —(reviewed on p. 153 of the *Indian Medical Gazette* for March, 1924). In African villages where the water-supply may sometimes be scanty, shallow wells constitute numerous breeding places for Anopheles; stocking with fish is better than oiling. Mosquito-proof wire gauze is a bad method of screening wells and water-supplies and receptacles, as it sooner or later gets broken or rusts. Instead an designed by Dr. Horn, and & Co., 110 Cannon Street, London, E.C.4 is much more suitable. Finally, with regard to West Africa, the incidence of yellow fever required investigation.

Sir James K. Fowler referred to the disappearance of malaria in the English fen country, and Professor Mühlens to its renewed prevalence in North Germany since the war. Dr. J. A. Le Prince had found mosquito "swatting" a useful measure in the Canal zone. Wire screening should not contain more iron than half of the 1 per cent. of alloy in the copper bronze used. He had heard of areas where there were supposed to be no Anopheles, yet when a horse was taken there as bait, it took three people all their time to collect the Anopheles that arrived to feed on it. Dr. Bass insisted that for the effective cure of a patient with malaria a course of 8 week's quinine treatment was absolutely necessary; and a further discussion took place on quinine therapy.

Dr. L. Beeche then described the health problems of Costa Rica and its public health organisation. In 1874 to 1890 when the railway from the capital to Port Limon was constructed, its course was literally strewn with corpses, as the result of epidemic malaria. Thanks to the work of the United Fruit Co. the countryside was now healthy and filled with a vigorous population. Yellow fever swept the country in periodical epidemics. In 1899 even reaching altitudes of 3,116 feet above sea-level; the disease has now been conquered and no cases have been reported since 1910. Dysentery, however, still contributes at least 2 per cent. of the total mortality, and 50 per cent. of the population harbour hookworms.

Frambæsia.—Dr. A. R. Paterson then dealt with the use of bismuth salts in yaws in connection with the anti-yaws campaign in Kenya colony. Towards the end of 1920 a large-scale campaign against the disease was instituted. In 1921 the number of patients treated with novarsenobillon was over 7,000; in 1922 it was over 25,000; but the cost of the novarsenobillon used was over £4,000 in the latter year. The campaign was proving so expensive that it was not clear where the funds were to come from. The value of potassium-sodium bismuth tartrate, containing about 54 per cent. of bismuth, was accordingly investigated. Its toxicity was very low and it was found to be an efficient spirocheticide. A dose of 0.6 gm. of novarsenobillon costs 3s.; the cost of the corresponding dose of the equally efficacious bismuth salt was 1/10th of a penny. The cost of treating 25,000 patients with bismuth was £15 as against a cost of £4,000 for novarsenobillon.

A discussion on yaws followed. Dr. Nichols described his early and well-known studies of the effect of salvarsan upon *T. pertenue*. Yaws and syphilis were quite different, and the former yielded more readily to treatment than the latter, also the two diseases differ in their clinical manifestations in experimental rabbits. Dr. P. W. Wilson related the history of yaws in Haiti. It was imported into the island in the early slave days, and the economic loss annually from it is now enormous. In

a population of 50,000 in one area there were over 5,000 cases: with a total population of $2\frac{1}{2}$ million in the island heavily infected, one could readily appreciate what an anti-yaws campaign was going to cost. The use of the bismuth salt, however, might render it practicable, even on an extensive scale.

Dr. Castellani spoke of conditions in Ceylon. In 1903 there were districts where it was impossible to get any labour, 80 per cent. of the children were infected, 30 per cent. of the adults, and the number of cripples was simply appalling. All that is changed now. With regard to differential diagnosis, late cases might be difficult, but "ring-worm" yaws was quite different from a circinate syphilide. Mercury was also useless in yaws. The chief drugs used in the campaign had been salvarsan, neo-salvarsan and Castellani's tartar emetic mixture. In summing up the discussion, Dr. Paterson mentioned that so far they had used the bismuth salt only by the intramuscular route.

Plague.—Plague was the next subject discussed. Dr. A. R. Paterson gave an account of the history of plague in Kenya Colony. Present in Central Africa at least as early as 1894, it was imported into Kenya in 1902. The local rodents are *Rattus rattus* (two sub-species), *Rattus norvegicus*, and *Rattus coucha uganda*, a Uganda species with 10 pairs of mammae on the abdomen of the female. The first was the all-important rodent in connection with plague, and there had been a regular steady invasion across country by this species, taking plague with it. In 1913 this wave reached the Yala river and there halted: plague was then prevalent only south of the Yala. In 1919, however, *Rattus rattus* crossed the Yala, and plague began to appear with it. In 1921 a survey was made by Mr. van Someren, who found that *Rattus rattus* was everywhere, that the natives regarded it as a species which was new to them, that it was ousting the indigenous Uganda rat. Several plague foci were discovered.

The most strenuous anti-rat campaign was now started, chiefly in North Kavirondo district where there had been between 1,500 and 2,000 deaths from plague in 1919. The chiefs and the inhabitants were called together and were informed by the District Commissioner that he would return in 4 days time and count the rats which they had collected. The indigenous African likes amusement, and he has apparently taken to rat destruction with zest. At the meeting on the 4th day, 5,697 dead rats were brought in by a large crowd of men, women and children, and the *tamasha* was completely successful.

After this, matters were organised on a large scale. The chiefs now collect the tails in bundles, and at district headquarters the tails for the district are counted and destroyed once a month. No rewards are given. Each chief is held responsible for an average of 5 tails per hut per month; if his tally falls short of this number he is "told off" for slacking. To a large extent rat destruction has now become a habit and part of the civilisation of the people. Destruction of rats is so planned as to start at the periphery of the infected areas and work towards the centre.

The campaign has now been in operation for nearly 3 years. What are the results? Plague was much less prevalent in the area in 1922 than in 1921, but this may have been due to other causes. The problem of carrying out rat destruction over an area of 4,152 square miles is obviously a difficult one; but many millions of rats have already been killed. Yet Dr. Paterson concludes that, even with this intensive campaign, so far as reducing the level of the rat population is concerned, "the campaign has probably been without effect." There are two possibilities: (1) infected rats may be being eliminated: or (2) an immune generation of rats may be being eliminated. The first would lead to the suppression of plague; the second, to its increase, and would do more harm than good. Only the future will shew which of these two possibilities is being accomplished; but at least it will now prove easy to start a very intensive campaign at short notice in any area.

Ankylostomiasis.—Dr. B. E. Washburn dealt with the economic value of a hookworm campaign. In the Vere area of Lower Clarendon Parish in Jamaica, a campaign was conducted during 1920. In 1915 to 1919 the average number of patients treated in the government hospital of the area was 78; in 1921 it was 57; in 1922 it was 52; and in 1923 only 45: whilst the number of beds in the hospital had been reduced from 80 to 50, with an approximate saving of £1,100 per annum. In 1919 the infestation rate in the area was 48 per cent.; on a re-survey in 1922 it was only 6 per cent. In Spanish Town there was a similar campaign in 1920–21. The number of cases of typhoid fever dropped steadily from 76 in 1919 to 29 in 1922 and 6 in 1923, a saving of £300 per annum on nursing, etc., in connection with this one disease alone. A questionnaire was sent to seven managers of estates on which anti-hookworm campaigns had been carried out; every one of them replied that there was an enormous improvement in their labour force; several of them assessed the increased output of work at 25 per cent. or more; intestinal diseases' incidence had markedly decreased; whilst the labourers' habits had become more sanitary. Many letters from cured patients were received telling of improved health and higher wages. Some of these epistles are quite amusing, (and recall a good story told by Dr. McVail. He had cured a boy of hookworm infection, and three weeks later the boy's father came to see him. "Sahib" implored the father, "please do not treat any of my other children, because that boy now eats so much that I cannot afford to feed him"!)). The results of the Jamaica campaign have been of marked economic value from the standpoint of the community, of the employer of labour, and of the individual.

Dr. Ashford said that formerly in Porto Rico they used to have terrible infections, on an average from 1,000 to 1,500 worms per patient, and ankylostomiasis accounted for one-third of the mortality, the total mortality being 42 per mille. Some 517,000 were treated out of a total infected population of 600,000. The results were amazing: the average hæmoglobin index rose from 43 per cent. to 72 per cent.: the death rate fell to 21 per mille; and the export trade of the island had improved from 8½ million dollars in 1900 to 80 million dollars in 1923. Sir Thomas Oliver mentioned the occasional outbreaks in the Cornish mines: it was supposed that ankylostome larvæ could not survive in the low temperatures of British coal mines, but he had found that they would withstand freezing. In Germany spraying with water was introduced in order to keep down the coal-dust and prevent explosions, but this had resulted in increased hookworm infection. When the Mont Ceni tunnel was constructed there was a heavy mortality among the workmen from ankylostomiasis: when the Simplon tunnel was constructed, the stools of every single workman were examined, and in the construction of this tunnel, 14 miles long, not a single death occurred from ankylostomiasis. Dr. Kofoid shewed from regimental records during the war how such epidemic diseases as measles were more prevalent among a lightly infested population with hookworms than among those hookworm-free. Tests shewed the mental efficiency of those infested to be 25 per cent. lower than that of those who were hookworm-free. Professor Fülleborn said that, whilst it was practically impossible to eradicate hookworm infection among coolies, yet it was practicable to so reduce the degree of infestation that immense improvement in general health took place; in some of the Dutch East Indian plantations the annual death rate among the coolies had fallen from 4 per cent. to 0.5 per cent. as the result of anti-hookworm measures.

Splenectomy.—Dr. B. M. Phelps commented on the neglect of splenectomy in the tropics. It is a valuable measure in pernicious anæmia, if not undertaken too late in the disease. He reported details of a case of splenectomy for a dislocated and enlarged malarial spleen which was causing pain and disability. The direct results were excellent, but the patient died elsewhere two years later, the cause of death not being stated. The possibility of sub-total resection of the spleen, as in operations on

the thyroid, was suggested. Dr. F. M. Johns reported excellent results after splenectomy in a case of pernicious anemia. Dr. E. I. Salisbury reported on a case of a dredge operator, found drunk and taken to jail; three days later it was realised that the man was acutely ill, with symptoms of an "acute abdomen." The spleen was found to be ruptured, and splenectomy was done with excellent results. Dr. Phelps drew attention to Krumbhaar's monograph on the subject, a record of 1,077 splenectomies for various causes, but with only 117 cases of probable cure.

Eye Diseases.—Dr. D. F. Reeder, in a paper, drew attention to the association of retino-choroiditis with an unbalanced diet in the tropics. Excluding cases due to syphilis, diabetes, Bright's disease and focal infections, such as sinus disease, there remained a residue of cases where the aetiology was obscure, but where a low carbohydrate diet gave excellent results. Colonel Ashford, Dr. R. C. Connor and Dr. W. M. James also gave accounts of similar cases. Dr. M. Arango discussed trachoma and pannus. He differentiated folliculosis from trachoma, although admitting that intermediate stages might exist. Follicular conditions of the conjunctiva were more marked in school-children and especially after the infectious fevers; 60 per cent. of them shewed enlarged tonsils, but very few of them errors of refraction. As contrasted with folliculosis, in true trachoma the elasticity of the conjunctiva is lost, there is hypertrophy of the membrane, which bleeds readily, trachoma follicles are present, and the secretion is watery, thin and acrid. Acute trachoma, so-called, is trachoma plus infection superimposed. Trachoma in its usual form is slightly contagious. Pannus trachomatous appears frequently in the form of vascular keratitis, but infiltration with adenoid cells in the layers of the cornea had also been observed. With regard to the control of trachoma, early diagnosis, isolation of the infected children, and disinfection of discharges and soiled articles were advocated.

Acclimatization in the Tropics.—Dr. F. L. Hoffman discussed the problems of mortality and acclimatization in the tropics. "It is my deliberate judgment that the main reason for the backward condition of the tropics is that, in a general way, these fertile regions have not as yet been drawn upon by modern nations as a matter of imperative necessity, and as sources of a needed food supply. When that time comes, the difficulties, which are now largely a matter of academic discussion, will tend to rapidly disappear." Reckless writers on tropical exploration had greatly exaggerated the climatic disadvantages and had created a general impression in America that the tropics were unduly unhealthy. The classical example of the construction of the Panama Canal ought to disabuse people's minds of such a view. The United Fruit Co. in 1923 employed in its tropical possessions 9,651 white persons and 44,986 coloured persons, including the families of employees. Its medical department had supervision of 158,213 persons. The death rates were 9.12 per mille for the white employees and 13.85 per mille for the coloured employees. Malaria was responsible for 38 per cent. of the admissions to hospital; dysentery was an important element in the death rate; venereal disease was perhaps next in importance to malaria; cancer shewed an incidence of only 0.67 per mille of the employees.

With regard to acclimatization of the white population, the first essential was a dietary study; most Europeans consumed a diet very unsuitable to the tropics. Most Europeans who died in the tropical area concerned died from non-tropical diseases. Steady work and regular exercise were important factors in keeping the white population fit. The abuse of alcohol was a most important cause of ill-health; whilst venereal diseases were a source of infinite mischief. Fourthly, every effort must be made to avoid parasitical infections, particularly malaria and ankylostomiasis. Science and engineering were conquering climate; if the white man could not be made fit for the climate, the climate might be made fit for him.

Sir Thomas Oliver spoke of the immense improvement of recent years on the Gold Coast of Africa, once regarded as "the white man's grave." Colonel Ashford contributed an interesting analysis of the causes of ill-health among a white population in the tropics; "there are people who come to the tropics who are unhappy because they cannot see the land they visit turned into a cheap imitation of the particular place from which they come, there are northern people who live in the tropics and have never known the soul of the tropics." Another important factor is nostalgia; a man from the North should have a change of environment every second year. A third element was the necessity for sufficient rest; the indigenous tropical inhabitant works "in low," whereas the immigrant white usually works at high pressure until he breaks down. Exercise was very important. Heat and humidity lowered the functional efficiency of the endocrine system in the white; the blood pressure falls and there is increased retention of nitrogen in the blood. Children should go Home undoubtedly. Dr. H. R. Carter drew attention to the many different climatic conditions present in different tropical areas. In the Canal zone they had found that the stenographers, teachers and nurses who did regular work kept well, whereas the housewives who idled all day were constantly on the sick list. Alcohol was of tremendous importance; it probably knocked out some 67 per cent. of the immigrant Americans and 32 per cent. of the British; "take all the exercise you can and as little whisky as you can" was a good motto for the white man in the tropics. In summing up the discussion, Dr. Hoffman spoke of loneliness as a very important cause leading to drink and gambling; fatigue was often due to lack of interest; there were certain psychological classes of persons who should never go to the tropics at all.

Sprue.—Sprue was the next subject to be discussed. Dr. Ashford said that, whilst typical sprue was unmistakable, there was a common class of case with a symptom-complex of disordered digestion, acid dyspepsia, constipation with occasional diarrhoea, diminution in the size of the liver, a shallow complexion, lowered blood pressure, asthenia and moderate loss of weight, sometimes a sensitive tongue and general nervous instability and irritability which was not sprue, but was not unlike its early phases. In none of such cases was *Monilia psilosis* found. In sprue this picture was still further enhanced, and *Monilia* could be found; he had even isolated it in such cases complicated with vaginitis or proctitis.

In typical sprue the enormous frothy stools might contain as much as 50 per cent of unabsorbed fat; abdominal pain was complained of in 40 per cent. of cases; nausea present in 43 per cent.; and in 25 per cent. occasional vomiting. Haematemesis and hyperchlorhydria are sometimes seen. The pathology of sprue was that it was an "atrophic inflammation." Sallowiness and anaemia were marked features, and in probably no other tropical disease was the loss of weight so rapid. An analysis of the urinary and blood chemical picture was then given in detail. Of 1,435 cases of sprue, two-thirds of them of moderate or severe grade, *Monilia psilosis* has been isolated in 83.7 per cent. The age incidence was chiefly between 20 and 40; 59 per cent. of the patients were females; and whilst it was the old resident chiefly who contracted sprue, there were numerous cases in persons who had been in the tropics for only a very short time. Sprue is an urban disease in the tropics, and is almost absent from rural areas. Socially it is a disease of the intellectual and well-to-do classes.

The underlying factor in the disease is nutritional unbalance. In Porto Rico, where sprue is very prevalent, the island, 3,606 square miles in extent, was inhabited by a population of 1,300,000 persons and most of its area given over to sugar, coffee and tobacco cultivation. The crops of foodstuffs grown on the island were hence in very scarce, eggs and poultry only seen in the towns, succulent green vegetables a rare commodity and the milk supply very scanty. As a result the diet in general

was defective in proteids, mineral salts,—especially calcium salts, and in vitamine A. The food deficiency in the island had created a vicious food habit, and carbohydrate excess resulted. It was on this basis that sprue supervened. To some extent, the disease appeared to be communicable.

Bacteriologically, the characters of *Monilia psilosis* were well established; those of *Monilia (Oidium) albicans* were not. The former was virulent to guinea-pigs, and the virulence could be greatly increased by passage. Finally a virulent strain was produced which, when administered in the food, caused fatal fermentative diarrhoea and buccal excoriation in these animals. The serological reactions of the organism also tended to incriminate it as the causative agent of sprue.

An interesting discussion followed. Dr. Castellani spoke of cases which had occurred in temperate climates, and the need in children of differentiating it from coeliac disease. He considered the role of the *Monilia* to be probably secondary. There was such a condition as true blastomycosis of the intestine, but the stools were quite unlike those of sprue and at postmortem ulceration of the gut was found. Most patients do well on a milk diet, but some 20 per cent. cannot stand a milk diet, and then a meat diet should be given. Large doses of bicarbonate of soda were often very useful. Sir Leonard Rogers said that he had usually found an oral streptococcal infection present in cases of sprue, and that the use of autogenous streptococcal vaccines had given very good results. Of 20 such cases so treated and followed up for at least a year after completing treatment, 18 remained well and at work in the tropics. (One patient whom the reviewer has personal knowledge of in this series developed sprue after he retired from India to Scotland, and reversed all the accepted canons of procedure by coming out from Scotland to Calcutta for treatment, and made a sound recovery on streptococcal vaccine and careful dieting.) Subsidiary lines of treatment are to administer vitamins, especially vitamine B in yeast or marmite; strawberries in the diet; bismuth salicylate and Dover's powder to control the fermentative diarrhoea. Dr. J. W. Stephens spoke of the difficulties in diagnosis; typical cases were easy to diagnose, but there was a big borderline group, which might or might not be sprue. Indicanuria is supposed to be a sign of sprue, yet is common in quite healthy persons. Acid saliva—another supposed sign—"is an exceedingly common normal phenomenon." Regulation of the diet and castor oil are useful measures in treatment. (The reviewer knows of one patient with sprue who tried a large round of eminent consultants, and then gave it up. He next treated himself for six months with regular small doses of castor oil taken systematically, and was apparently completely cured, or else recovered spontaneously.) Dr. Agramonte spoke of the importance of rest; he would not undertake a case unless he could send the patient to bed. Dr. Ashford, in closing the discussion, insisted on the primary rôle of *Monilia psilosis*; tetany is seen in some 25 per cent. of cases; as regards the differential diagnosis from pernicious anaemia, there is not the same rapid wasting in the latter disease; the dietetic syndrome is apparently the background of the picture in sprue, but does not account for its aetiology; 95 per cent. of cases may be allowed a liberal diet, the other 5 per cent. must have either a whole milk or whole meat diet. Calcium salts, pancreatin and diastase are useful remedies in treatment.

Pellagra.—Dr. Seale Harris next read a paper on pellagra. He concluded that an unbalanced diet does not seem to be the only factor in the aetiology of this disease, but it is an important predisposing cause, a diet low in vitamine C and unbalanced, with an excess of carbohydrates being the underlying picture. In treatment a full diet, rich in vitamins, particularly vitamins B and C, with a low carbohydrate content, and eliminating cane sugar entirely is important. The true cause of pellagra has still to be discovered; it is probably due to an infectious agent of some kind.

Insulin.—Professor T. G. Banting followed with a paper on insulin, which constitutes a classic; in nine brief pages he here presents a concise and authoritative summary of the subject; indeed it constitutes—to quote a hackneyed phrase—"what the physician ought to know about insulin." In diabetes mellitus the functional ability of the islet cells of the pancreas is impaired by nerve strain, infections, changes in blood supply, over-activity, etc., and there is no reserve. In such individuals therefore, when sugar is given in large amounts, it remains circulating in the blood stream at a higher percentage and for a longer time than in normal individuals. This increased percentage of sugar in the blood is recognised by the kidneys, and sugar is excreted in the urine. The hyperglycæmia thus produced gives rise to thirst; the large amount of fluid consumed to combat the thirst gives rise to polyuria. Since the tissues are under-nourished from failure to burn sugar, there is increased demand for food, and hence excessive hunger. The increased intake of food throws a still greater strain upon the insulin-producing mechanism and there results a vicious circle of disease, with consequent emaciation. Hence the classical symptoms of the disease. Acidosis supervenes; in children and young adults the disease is usually rapidly fatal; in adults of middle age and in old age the development of the disease is slower.

The fundamental principle in treatment is to give only the minimum amount of carbohydrate necessary for life and to give it in such a form that the pancreas can deal with it; whence the Allen, Woodyatt, Wilder and other special diets. The basal requirement of the individual in diet is about 25 calories per kilo of body weight per day. Protein and carbohydrate can supply 4 calories per gramme, fat 9 calories per gramme; but the rôle of fat is limited by the fact that without carbohydrate it cannot be completely oxidised, and that of protein by the fact that 46 per cent. of it may produce ketone bodies, and 56 per cent. of it may be converted into carbohydrate.

Complete co-operation between patient and physician is the first essential in treatment. The patient must be taught elementary urine analysis and the calculation and preparation of his diet. The full history of the case should be enquired into, and a complete physical examination made, especially with a view to discovering any possible focus of chronic infection, which must be dealt with if found. He is then placed upon a basal diet for 3 or 4 days or until the urine is sugar-free. As soon as he becomes sugar-free or when the blood-sugar level reaches normal, the caloric intake is gradually increased until sugar appears in the urine; if he remains sugar-free or has a normal blood-sugar content on a diet containing 700 calories over and above his basal requirements, the case does not need insulin.

If insulin is required, a beginning should be made with a dose of not more than 5 units twice a day; which should be given 20 to 30 minutes before the morning and evening meals in order to combat the hyperglycæmia following the food intake. If three meals a day are taken the morning dose should be larger than the evening one, in order to cater for the midday meal as well as breakfast. When the dose of insulin and diet are so balanced that the patient's blood-sugar is normal, they are concurrently increased until the required amount of food is reached. If too large a dose of insulin be given, symptoms set in in from 1½ to 6 hours, usually about the 3rd or 4th hour. Unaccountable anxiety, restlessness and profuse perspiration are first noticed followed by hunger, clonic tremor, pallor of the skin, a rapid rise in the pulse rate to 120 beats per minute, rapid fall of blood pressure, dilatation of the pupils, aphasia, then collapse, unconsciousness, convulsions and finally death may occur. The immediate treatment should be to at once administer glucose as orange juice, or sweetmeats, or if the symptoms be severe to inject adrenalin, which combats the insulin effect.

In the case of a patient admitted with diabetic coma, the urine should be obtained by the catheter and rapidly analysed, together with a rapid analysis of the blood-

sugar. Whilst these tests are being carried out, the bowels should be evacuated by copious enemata. If sugar and acetone are present in the urine in large amounts, from 30 to 50 units of insulin should be immediately given subcutaneously. The patient usually regains consciousness in from 3 to 6 hours. The next stage is the need for caution. Blood and urinary sugar should be frequently estimated in order to guard against insulin over-dosage and the danger of hypoglycæmia. The patient should now take fluids and glucose by the mouth—at least 200 c.c. of fluid per hour. The next day the white of an egg in 200 c.c. of orange juice may be given, or protein every 4 hours, until the patient is on a balanced insulin-diet treatment; he is thenceforward treated as an ordinary diabetic.

Not only is insulin the sheet-anchor in the treatment of diabetes mellitus, it will convert bad surgical risks in such patients into good ones. But "insulin is not a cure for diabetes; it is a treatment."

Dr. Seale Harris congratulated Dr. Banting on his simple but masterly exposition of the subject. In Birmingham they had treated over 100 cases with insulin during 18 months and had kept careful records. Cases of coma and gangrene which formerly would have died had been saved, and operations rendered possible which otherwise could not have been attempted. Hyper-insulism was caused by over-ingestion of sugar, until finally the islet cells having become worn out, hypo-insulism set in, with diabetes in its trail. Such diabetics often shewed obesity due to over-eating preceding the onset of diabetes. Dys-insulism might also follow infection of or trauma to the pancreas. Ulcer of the stomach or duodenum might lead to co-existing disorder of the pancreas. With hyper-insulism might go hypo-adrenalism, whilst with disturbance of the insulin mechanism might also go disturbances of other endocrine glands.

Cancer.—Sir Arbuthnot Lane then read a paper on the causation of cancer, summarising in a few pages his well-known views on the correlation between chronic intestinal stasis and cancer. A considerable discussion followed. Sir Arthur Newsholme enquired why, if cancer was especially associated with constipation, should cancer of the tongue be five times as prevalent among males than among females, who are in civilisation at least, the more constipated sex? Also why is there more intestinal cancer among males than among females? Sir James Fowler said that it was very difficult to over-emphasise the importance of local irritation. There was a general policeman, the general defensive mechanisms of the body; and a local policeman, the local resistance of the tissues; the latter might be put out of action by local irritation. Cancer is uncontrolled cell activity, and when we know more about the causes of cell activity and cell health, we may know more about the origin of cancer. Sir Thomas Oliver hoped that, as we are now able to grow cells and tissues apart from the body, thanks to the researches of Carrel and others, we might soon be in a better position to tackle the cancer problem. Dr. F. L. Hoffman confirmed Sir Arbuthnot Lane's views as to the rarity of cancer in primitive races. In San Francisco he had found that a considerable proportion of the men who died from cancer had been exposed to smoke or fumes in industrial occupations. On the other hand in investigations in Eastern Bolivia he had never come across a case of cancer of the breast.

Alastrim.—Dr. L. M. Moody described an epidemic of alastrim in Jamaica. Clinically the disease in general resembles mild small-pox, but the rash is even more profuse. There are two types of lesion in the rash; either large and discrete pocks, or pocks which are small and closely set; sometimes a mixture of both types occurs in the same patient. The course of the rash is rapid, and in many cases in 14 or 15 days the crusts have separated. Mortality was very low; 13 deaths only in 2,912 cases; including 2 deaths in pregnant women. The disease is transmissible to the fetus in utero. Vaccination of contacts proved a very valuable measure in prophylaxis, but does not appear to

give absolute protection. Dr. M. J. Rosenau said that he did not consider the differences between mild small-pox and alastrim sufficient to warrant regarding the latter as a separate disease; it was well known that small-pox epidemics varied very greatly in virulence. Vaccination and other measures against the so-called alastrim should be as vigorous as any taken against small-pox. Dr. W. H. Park drew attention to Brill's disease as a mild type of typhus and its analogies with the relationship of alastrim and small-pox. Dr. Castellani advocated 1 per cent. solution for the face and painting with . . . for the limbs in treatment.

Leprosy.—Leprosy was next discussed, the subject being introduced by Sir Leonard Rogers in a paper on treatment; which is a model of what such papers should be, concise, yet clear and informative. He outlined the history of the evolution of the ethyl esters in the treatment of leprosy. In former times all sorts of remedies were in vogue, mineral preparations, iodine in various forms, local treatment of the lesions, sera, tuberculin, the nastin treatment, vaccines of acid-fast bacilli—none of which was probably the true lepra bacillus, and vaccines made from excised leprosy nodules. But the one remedy which had stood the test of time is chaulmoogra oil, originally produced from the seeds of *Tournefortia kurzii*, but now also obtained from *Hydnocarpus wightiana* and *H. anthelmintica*. Given orally, this is the oldest of all remedies for leprosy and its use is attended with some improvement, even occasionally cure; at present trials are in hand of administering fresh nuts of *H. wightiana* orally. The active principle in the oil is gynocardic acid, a mixture of the lower melting-point fatty acids of the oil, and first separated by Moss in 1879, and at first used orally also.

Tournefort was the first to use chaulmoogra oil intramuscularly and reported apparent cures. Dr. V. G. Heiser used intramuscular injections of equal parts of chaulmoogra oil with camphorated oil and resorcin. As a result of his success, Sir Leonard had had sodium gynocardate prepared for him, and with the help of Rai Dr. Chuni Lal Bose Bahadur and Dr. Sudhamoy Ghosh in Calcutta had subsequently had prepared a whole series of derivatives. Eventually he concluded that the salts of the whole of the fatty acids of *H. wightiana* gave better results. After injections, excised nodules shewed lepra bacilli breaking down in myriads in the tissues, and steady clinical improvement was the rule with the patients. Intravenous use of the gynocardate then came to replace its intramuscular use and sodium morrhuate from cod-liver oil and sodium soyaate from soya bean oil followed. With the gynocardate and similar treatments in patients treated for from 3 to 12 months, in 40 per cent. of patients the lesions had all cleared up, and in another 40 per cent. there was marked improvement.

The intravenous use of sodium hydnocarpate, however, was liable to have an irritant action on the vein, and accordingly the ethyl esters of the different fractions of the fatty acids of chaulmoogra oil were next introduced for intramuscular use; whilst Dr. Muir introduced "E.C.O.", consisting of equal parts of ethyl hydnocarpate, 4 per cent. double distilled creasote and pure olive oil. This is either given intramuscularly or the attempt is made to infiltrate the leprosy lesions with it by injection. In 13 leper asylums, to date, on 300 cases the results reported are 72 per cent. improved and 32 per cent. greatly improved in from 2 to 12 months of starting treatment; and 100 per cent. improved and 52 per cent. greatly improved in patients treated for from 6 to 12 months. In Hawaii, of 310 cases admitted 172 were discharged cured on parole, and it is hoped to have reduced the incidence of leprosy in the island by 45 per cent. within a decade. In fact the freeing of a given area or country from leprosy is becoming a practicable proposition.

Sir Arthur Newsholme contributed a note on the causes of the historical reduction of leprosy in

temperate climates, shewing how in Norway institutional segregation of lepers, following upon the introduction of compulsory notification of the disease, had reduced the incidence of the disease from 181 cases per 100,000 of the population in 1856 to 22 per 100,000 in 1905, since when it has become an increasingly rare disease.

Tuberculosis.—Sir James Kingston Fowler then read a remarkable and very interesting paper on tuberculosis in the tropics. Taking the analogous case of yellow fever on the West Coast of Africa, it practically never occurred among the negroes, but was confined to the immigrant and non-immune white; the former were immune, the latter not. The view was widely held that the increasing decline in tuberculosis in European countries was due to widespread mild infections in infancy which were recovered from, leading to the vast majority of the adult population being immune to the disease. "The future of tuberculosis prevention" writes one authority "lies in the deliberate exploitation of immunisation, by means of vaccinating doses of dead or attenuated bacilli." Mirauer recorded 88 per cent. of 145 non-tuberculous persons as having given a positive tuberculin reaction, but such a course is not devoid of danger. In phthisis, tuberculin is the worst of all "remedies" and a case of quiescent fibroid phthisis was cited in which an injection of tuberculin had been followed by the expectoration of four calcareous particles, invasion of another portion of lung tissue and fresh cavity formation; also of a man whose life had hung for 40 years on the integrity of a fibrous capsule around a caseous mass and who, when the capsule gave way, was dead in 28 days from acute miliary tuberculosis of the lungs. Some years ago, Sir John Rose Bradford had asked him what was the incidence of obsolete tuberculosis lesions in general postmortems. "In about 9 per cent." was the answer. "I thought you would say 90 per cent.," replied Sir John, "it is curious that that is the exact figure obtained from an analysis of 2,121 postmortems at Etaples," during the war on soldiers who had died from various causes or who had been killed. Martin's incidence figures at postmortems at the Middlesex Hospital from 1890 to 1891 gave the same figure, 9.4 per cent. On these findings where was the evidence that in European countries some 90 per cent. of the population acquired mild tuberculosis in infancy, to be followed by immunity in later life? There were some well-known old English families with magnificent constitutional physique; the men of which only began to feel old at 90, and died at about 96 years of age, apparently chiefly out of consideration for the claims of the rising generation. Local proverbial wisdom said that the only way to kill them was to poleaxe them. Was such a state of affairs due to acquired tuberculosis in infancy? He thought not. The diminution of recent years in tuberculosis was the result of other factors, better housing, better sanitation improved public hygiene.

On the other hand, when tuberculosis invaded virgin soil in non-immune Asiatics, it played havoc. At general postmortems on patients from the Asiatic labour corps in France during the war, there was no evidence of obsolete tubercular lesions,—quite the contrary. But the incidence and death rate among them from phthisis were awful. The following figures shewed a most striking contrast:—

	Annual case incidence per 10,000 strength.	Annual deaths per 100,000 strength.
S. African Labour Corps	.. 186	167
Cape Colony Labour Corps	.. 444	88
Indian Labour Corps	.. 142	53
Chinese Labour Corps	.. 36	12
British Army in France	.. 10	0.5

He did not consider that the best way of creating an A1 population was to vaccinate them all with dead or attenuated tubercle bacilli. Passing on to measures to be taken to deal with tuberculosis in the tropics, the

value of compulsory notification was a moot-point; it was of no value when the patient was almost dead. He knew of no specific remedy of any value. Hospitalisation often made a mild case worse. What were wanted were not hospitals, but tuberculosis settlements, a scheme for which he outlined, where, together with the necessary sanatorium and hospital departments, you would also have industrial departments, open air cottages and hostels, workshops, and training in handicrafts; in other words a colony. The tuberculosis problem is, to a very large extent, a housing problem all over the world. "Any country that rejects compulsory vaccination and retains its slums must pay for small-pox hospitals and tuberculosis settlements."

In opening the discussion, Dr. H. C. Clark said that whereas the course of tuberculosis was usually measured in years in the case of white races, it was a question of months in the coloured races. Hardly a single case among the latter shewed evidence of healed tubercular lesions at postmortem examination, and miliary tuberculosis of the lungs usually set in early and soon carried off the patient. Dr. W. M. James assessed the case mortality of phthisis among the coloured population in the Panama Canal zone at 100 per cent. He was sorry to hear Sir James Fowler speak as badly of immunisation, because there was at present so very little that one could do for these unfortunate victims. Dr. R. C. Connor related the history of a medical officer of health in Panama who was an enthusiast about tuberculosis, and who tackled the slum question in earnest. His work progressed rapidly until he came to tackle the wealthier quarters of the city; then he was transferred elsewhere and his successor dropped the programme. Sir Thomas Oliver was surprised at Sir Kingston Fowler's postmortem figures; knowing the distinguished position which the latter held as a pathologist they must be accepted as reliable; but at Newcastle the pathologists informed him that the incidence of tubercular lesions at all postmortems was in 75 per cent. of bodies, whilst at the Morgue in Paris it was 90 per cent. Tuberculin could not be entirely discarded; but it must only be used for very carefully selected cases. Dr. W. E. Deeks remarked that he always sent white patients who contracted tuberculosis in the Canal zone to a high dry climate such as that of New Mexico. In 15 years he had only known of one death amongst them.

Influenza.—Sir Thomas Oliver introduced the subject of influenzal pneumonia. The most striking feature of epidemic influenza was the tendency which it showed to vary from time to time in type and in its severity; one epidemic might be of gastro-intestinal type with low mortality; another of broncho-pneumonic type with high mortality. The death rates in France from influenza during the great war were tremendous; in 1918 the French army lost 9.38 per mille of its soldiers from it. In the severe types what was present was not lobar pneumonia so much as broncho-pneumonia, often with a minimum of recognisable signs, but with profound toxæmia and necrosis of the mucous and submucous layers of the bronchioles. The disease was also important in awakening to activity old and latent tuberculosis.

Dr. M. J. Rosenau said that at the outbreak of the great pandemic they all thought that Pfeiffer's bacillus was the cause of influenza. They collected 99 healthy volunteers from the Navy and with some trepidation started painting their throats with pure culture of this organism, giving it in sprays to them to inhale, and nothing happened. Collected mucus from the nose and throats of influenzal patients also proved to be innocuous. It also failed to produce the disease when injected subcutaneously. Apparently the virus was so delicate that it died very rapidly after leaving the body. Next, arrangements were made for each volunteer to sit close up, face to face, with an influenzal patient and to breathe in his expired air. None of them contracted influenza, although some of them contracted a septic sore throat. He did not want to infer that the virus

was not present in these secretions, but there were factors underlying its spread which we did not understand. Dr. W. H. Park spoke of the rôle of traffic in spreading the infection. As to the micro-organisms concerned, everything depended on the bacteriologist; one man would always find Pfeiffer's bacillus, another always streptococci, "change the bacteriologist and you change the bacteriological findings." He considered Pfeiffer's bacillus merely as a secondary invader. Dr. Hoffman drew attention to the 66 weeks' cycle of influenza epidemics as a phenomenon which required explanation. Sir Arthur Newsholme pointed out that in the 1890-91 epidemic the disease chiefly affected old people; whereas in 1918 its chief incidence was in young adults. Dr. Scale Harris said that America blamed Europe for her influenza epidemics, whilst Europe blamed America for hers. The 1890-91 epidemic was said to be "Russian flu," that of 1918 "Spanish flu." New York was the chief distributing station for the Southern States. MacCallum had found that if two cages of rats were placed side by side under similar conditions of exposure to lung infections, but given different quantities of vitamine A, the ones with deficiency in vitamine contracted the diseases, the others did not. Dr. W. E. Deeks spoke of mercurochrome intravenously as having given brilliant results in post-influenzal pneumonia, also in gonorrhœal rheumatism. The drug is administered in a 1 per cent. solution, and 1 c.c. given for each 10 lbs. of body weight. There is usually a more or less severe reaction, with fever rising to 106°F. or so, but thereafter as a rule rapid resolution.

Pneumonia.—Dr. W. H. Park then discussed the value of antisera in pneumonia. Pneumonia was probably responsible for more deaths in the world than any other disease. In 1923 among the employees of the United Fruit Co., the death rates per mille were from pneumonia 5.5, from tuberculosis 2.2, from dysentery 1.9, and from malaria 1. The pneumococci are divisible into a number of types, and vaccination of an animal with one type causes it to produce an antiserum for that type, but for no other type—at least as far as therapeutic efficacy goes. Intravenous injections of the antiserum so produced in a case of pneumonia will prevent invasion of the blood by the type concerned and matching the serum, and, with few exceptions, will sterilise the blood which has been invaded. As it is chiefly the septicæmic cases which die, such serum should be of value in treatment. Cases of pneumonia due to type 1 treated with type 1 serum showed a marked reduction in mortality; a death rate of 9 per cent. as against one of about 20 per cent. for untreated cases. Felton in 1924 had discovered a method of refining and concentrating the serum by precipitation of its globulins with distilled water, collecting the precipitate, and re-dissolving it in maximal concentration; the concentration being some ten times the original in potency. Sometimes a chill followed the intravenous administration, but different preparations varied in this respect.

In treating a case, if possible, the strain of pneumococcus concerned should be typed. A first dose of 5 to 10 c.c. of the polyvalent antibody for types 1, 2, 3 and any other dominant strain could then be given. The pneumococci causing pneumonia should be studied in each region, so that there would be available the type antibodies needed for the cases concerned. (In India, as our readers know, this investigation is now being carried out by the Army authorities, also by Capt. Malone at Parel and by Colonel Cunningham at Madras.) Up to the present, type 1 cases seem to respond better to type 1 serum than do type 2 and 3 cases to their corresponding sera, whilst type 2 cases correspond better to their sera than do type 3 cases. Felton's work, however, renders the high concentration of antisera possible and better results may be looked for. The potency of each phial should be marked on it, and for this purpose it was desirable to introduce some standard world unit in which to express potency.

Dr. Rosenau gave an account of Felton's work. Dr. Nichols stated that the use of type 1 serum in a type 1 epidemic had reduced the mortality from 30 per cent. to 7 per cent., and the number of funerals shewed an inverse relationship to the available supplies of the serum. In the U. S. A. Army they had tried anti-catarthral vaccines and vaccines of *B. pneumosintes*, the supposed cause of epidemic influenza; and when influenza came along it was those vaccinated that it picked out first. They had also tried oral vaccines in the natural paratyphoid B infection of guinea-pigs and they gave no protection. If another great influenza epidemic were to come along to-morrow, we should not be much better off than in 1918; only this time we should keep all the patients strictly in bed and make considerable use of the sera of convalescent persons. Major Dunham spoke of the extensive use in the American Army of a mixed vaccine of types 1, 2, 3 pneumococcus, Pfeiffer's bacillus and streptococcus; 6,000 soldiers were given the vaccine and some 14,000 were unvaccinated controls; the results were negative. Dr. W. H. Park, however, reported good results in using vaccines against lobar pneumonia. The vaccine consisted of 2,000 million each of types 1, 2, 3 pneumococci, 2,000 million streptococci, and 1,000 million influenza bacilli per dose, and 3 doses each were given to 1,536 employees of the Metropolitan Life Insurance Society; whilst 3,025 uninoculated people acted as controls. Two cases of pneumonia occurred during the next three months among the uninoculated, none among the inoculated. At an asylum for insanes, 3,000 patients were taken and half of them inoculated, the rest acting as controls. During the next year there were 6 cases of pneumonia in the controls as against 3 in the inoculated. The author concludes that a short duration immunity is apparently conferred.

Bronchitis.—Dr. Castellani then gave an account of the causes of hæmorrhagic bronchitis of non-tubercular origin, instancing no less than 18 causative micro-organisms as responsible for such conditions. In bronchial spirochaetosis, the diagnosis is established by examining the sputum collected after a preliminary rinsing of the mouth; it is found to be swarming with spirochaetes. For the acute cases aspirin and codeine are useful; for sub-acute and chronic cases tartar emetic orally, arsenical preparations, and potassium iodide occasionally. Bronchial anæbriasis (without accompanying liver abscess) has recently been described by several authors. Broncho-mycosis may be due to one or other of a large number of these fungi, the chief genera concerned being *Nocardia*, *Monilia*, *Aspergillus* and *Sporotrichum*. Potassium iodide in large doses plus autogenous vaccines appear to be the best lines of treatment. Experimentally, in animals given intravenously or intraperitoneally to rabbits and guinea-pigs. Other strains proved non-virulent, whilst with some others, on intravenous or intra-pulmonary injection, a peculiar nodular condition of the lungs was produced. Cultural investigation of the sputum was called for in all cases, with sugar tests to determine the species present. "Tea-factory cough" is probably an instance of pulmonary moniliasis, due to the inhalation of spores of the fungus when inhaling tea dust. A very complete account is given in the paper of all the species concerned, fully illustrated by plates shewing their morphology and cultural characteristics, whilst the paper ends with a very useful bibliography. Dr. F. M. Johns said that far too much reliance was placed by physicians on the x-ray diagnosis of phthisis; cases shewing hazy shadows might be cases of broncho-moniliasis. Dr. Iturbe recorded having found *Paramonimus westermanni* in the lungs of dogs; the intermediary hosts are a snail, *Ampullaria luitostoma*, and a crab, *Pseudotellphusa iturbei*, and an account of the life history of the parasite was given. Colonel Ashford related the history of a patient intestinally infected with *Monilia psilosis*, who had suddenly developed an abscess of the lung due to this organism,—the case finally clearing up on an autogenous vaccine of this organism.

Dr. A. A. Facio said that in some instances of supposed bronchial spirochaetosis, great improvement had taken place after injections of neosalvarsan, yet the sputum still shewed the same spirochaetes as before, in some instances for as long as 2 months after completing treatment. Dr. H. C. Clark considered that many cases of mycotic disease of different organs were overlooked or misdiagnosed; our knowledge of the subject was still rudimentary.

Measles.—Dr. W. H. Park read a paper on the use of convalescent plasma in cases of measles. The observations recorded were made in New York over a period of three years. Blood from 60 adults who had recently recovered from attacks of measles and who were Wassermann-negative were collected, and the whole plasma used. Over 1,500 children received preventive injections of 3 to 10 c.c. on exposure to infection; during a period of six months accurate records were obtained in connection with 979; 84 per cent. escaped the disease as against 52 per cent. of others in the same families not so treated. The dose should be 6 c.c. for a child under 3 years of age who has been exposed to infection and 10 c.c. for a child over that age. Immunity is given for one month, and in order to obtain the most potent serum the convalescent should be bled very shortly after convalescence.

Pathology.—Dr. F. B. Mallory pleaded for the encouragement of pathological work in the tropics. The physician's mistakes are often brought to light only in the postmortem room, and instances were quoted of miliary tuberculosis mistaken for chronic myocarditis; of a lesion of the hand due to chronic yaws mistaken for carcinoma. The accumulation of material and observations will help in very many still unsolved problems. Dr. R. P. Strong contributed a valuable paper on the development of pathogenicity and parasitism. If we are to take long views, we must regard parasites as being just as much subject to evolution as their hosts; and it is probably true to-day that, as in the past, so now many free living or saprophytic living forms are acquiring the habit of parasitism. Among the nematodes a number of examples occur; thus *Strongyloides* shews an adaptation to both free living and parasitic generations. In the case of *Aphelenchus*, a small nematode which causes "red ring" disease in cocoa-nut palms, free living forms have acquired parasitic properties towards plants. The spirochaete of Vincent is usually non-pathogenic, but under conditions of local lower resistance becomes pathogenic. The free living spirochaetes of stagnant water and filter beds had until recently been regarded as non-pathogenic; now Zuelzer and others have shewn that among such spirochaetes were leptospirae, morphologically identical with *L. icterohaemorrhagiae* and capable of causing symptoms resembling those of Weil's disease on injection into guinea-pigs, after long cultivation in media containing serum. Rickettsiae were in some instances pathogenic, in others not; this group of organisms appeared to be natural parasites of insects, which are now in course of evolution in some instances into pathogenic parasites of vertebrates. The apparently natural flagellate forms in the mid-gut of certain *Triatomas* in South America, when injected into laboratory animals developed into the trypanosome of South American trypanosomiasis. The *Herpetomonas* of *Euphorbia* were normally not pathogenic to laboratory animals. But what are apparently these same herpetomonads are also found in the Hemiptera feeding on infected plants and in lizards on such plants which feed on the Hemiptera, and the flagellates from the lizards in some instances proved pathogenic to monkeys. It would appear as if the flagellate, in transit from plant through insect and lizard had acquired properties of virulence.

Records.—Sir Arthur Newsholme next read a paper on the bearing of disease records in public health work. Theoretically it ought to be possible to eradicate a disease, such as malaria, by the right hygienic measures without knowing anything about its incidence and distribution; actually such knowledge was the corner-stone

on which efforts for the prevention of disease were based. In the old days it gradually became recognised that had conservancy meant epidemic intestinal diseases; with improved conservancy in England cholera dwindled and the enteric incidence fell. Then came the knowledge of the carriage of such diseases by water-supplies, milk supplies and through oysters and fish, and finally the discovery of the carrier state; each discovery being followed in turn by the application of fresh precautionary measures with an ever lessening incidence of the disease. Typhus had disappeared from Great Britain long ago, but had its transmission by the louse been known, it could have been eradicated far more rapidly. In a manner the sufferings of the sick are the vicarious means of reducing and abolishing the sufferings of others. In the presence of a big epidemic, fear is the most notable stimulus towards an improvement of public health. With regard to the notifiable diseases each case should be regarded as the potential starting-point of an epidemic and should call for protective measures; and field work becomes the most essential element in the practice of preventive medicine. The laboratory is a valuable auxiliary, but the clinician and the public health official also come in; no source of information should be neglected, and co-ordination should be the order of the day; a mere ideal plan drafted in an office was useless.

Sir Thomas Oliver drew attention to the use by anti-vaccinationists of the decline of tuberculosis before the discovery of the tubercle bacillus, and of the eradication of typhus in Great Britain long before the discovery of the louse transmission of the disease in their campaign against vaccination. Major Dunham said that it was impossible to practise preventive medicine from an office desk. In the American Army they made their bacteriologists serve on the clinical side. Sir Leonard Rogers spoke of conditions in India, where records were available for the British and Indian armies, and for jails, which could be relied upon, for the past 50 years. The figures for the general civilian population were far less reliable. Dr. H. R. Carter pointed out that in a number of cities in South America fairly accurate statistics as to causes of death had been kept right away from the 17th century in the Spanish archives of the mortuaries, the "*libros de defunciones*." Those ancient scholar priests did their work well; for instance he had come across accurate records of 1,014 deaths having taken place in one day in the little town of Forteleza in Brazil from the combined effects of epidemic small-pox, drought and starvation.

Publications.—Dr. H. J. Nichols then read a paper on the needs of publication in tropical medicine; (a paper which has given us much food for reflection and which we wish that we could reprint almost verbatim). Practically speaking the science of tropical medicine is to-day about 30 years old. The output is enormous and is rapidly increasing, but "scientific records are apt to be the last to be established and the first to feel the cut of economy," (as readers of the *Indian Journal of Medical Research* know only too well, as the result of the misapplied zeal of the Inchcape Retrenchment Commission). What is called for is *thoroughness*. First on the part of the individual contributor; he must so prune, trim, and polish his manuscript that it shall be a model essay, concise, clear and brief; there is no room for egotism in medical journals, there is no space for the reproduction of a 'cinema film' of the laboratory work, and it is unnecessary to review the literature on the subject "back to the year one." Given important reports on medical research work in tropical medicine, however, where is the author going to find publicity? He may be fortunate enough to find acceptance in such general and splendid journals as the *Lancet* or the *British Medical Journal*, but the editor of a general journal cannot be expected to give much space to exotic subjects. Then come the special medical research journals; admirably run—most of them—(especially our new contemporary, the *American Journal of Tropical Medicine*, if we may be permitted the remark)

but costly and hardly a business proposition. Reports of organisations, such as the present volume under review, are a third source of publicity, but of limited general circulation. Government reports are avenues for publication where anything of value tends to be buried under a husk of routine matter and ultimately pigeon-holed. (The pioneer work of D. D. Cunningham and Lewis in India on the entamœbæ, cholera, trypanosomiasis and several other subjects is a good illustration; it is to-day buried and almost inaccessible in the annual reports of the Sanitary Commissioner to the Government of India for the years 1870-1880.) Proceedings of learned societies are another source of publicity and often a valuable one, as in the *Proceedings of the Royal Society of Tropical Medicine and Hygiene*. Finally, this enormous output, published in some dozens of different journals, etc., all over the world requires digesting for the ordinary reader. Here, luckily, there are the altogether admirable *Tropical Diseases' Bulletin* and the *Bulletin de l'Institut Pasteur*, one or both of which are absolutely essential to all serious students of tropical medicine. Philanthropists to-day endow institutions and schools of tropical medicine; the need for the endowment of journals of tropical medicine has not yet been recognised, but is a most pressing one. (The volume under review is an admirable example of how to do it.)

(If we may be permitted comment on Dr. Nichol's paper, it is to say that a medical journal in the tropics requires the collaboration of a capable editorial staff with business ability, and, as both are unlikely to be met with in the same individual or individuals, different individuals should represent both interests. If one can further secure a good status of publisher, so much the better. It is the advertisements which pay for the cost of publication of a journal, and no proprietor of a medical journal can afford to let this side of the matter drop. On the other hand, it is the status of the journal and its circulation that attract the advertisers, and this depends upon the quality of its literary matter. It would be ideal to get some broad-minded philanthropist to subsidise a medical research journal; it is more stimulating to face the struggle for survival.)

In the discussion which followed Dr. Nichols' paper, it became clear that two types of journal are wanted; the first the journal for the general practitioner, which shall be elementary but shall review as wide a field as possible; the second the journal for the research worker and specialist, which is bound to have but a limited circulation and will probably not pay. An interesting suggestion thrown out was that the successful journal of the first type should run or subsidise journals of the second type. Finally, speakers appeared to be unanimous on one point; where a contributor of a long or important paper sends it in, he should also send in with it a brief summary suitable for abstract or republication in more general journals.

The Gorgas Institute.—Dr. E. Zubieta then gave an account of the proposed Gorgas Institute of Tropical Medicine, to be established at Panama in memory of the splendid work of Major-General Gorgas during the construction of the Panama Canal. We confess that Dr. Zubieta's account makes our mouth water. There is to be a hospital of 750 beds, costing 3 million dollars, which was to have been opened last September. Six million dollars are to be spent upon the associated institute of tropical medicine. This is "some" scheme, though in no way more than adequate for the needs concerned. But in parsimonious India we think in terms one-tenth or one-twentieth of those which the enterprising business and medical organisations of Central America consider normal. The functions of the institute are to be three-fold; it will be primarily a research laboratory in tropical medicine and hygiene; secondly it will be a school for post-graduate instruction and distribution of scientific and medical literature to workers throughout the tropics. Lastly, it will be a fitting memorial to the immortal work of Gorgas in

the Canal zone. During the French attempts at construction of the canal in 1870 to 1880, no less than 22,189 labourers died of disease, chiefly from malaria, dysentery and yellow fever, and the death rate was about 65 per mille per annum. Gorgas and his colleagues abolished yellow fever from the area; they reduced the malarial incidence to such a pitch that there were only 12 admissions for this disease in the last month for which figures are available—June, 1924; whilst the dysentery incidence has been reduced to about one-eighth of what it was. From the account which Dr. Zubieta gave of it, however, the Gorgas Memorial Institute will be no unworthy memorial to that great pioneer.

Military Medicine.—Major Dunham then gave an account of the work and organisation of the medical department of the U. S. A. Army in the tropics. Of a total strength of 134,808 officers and men of this army, 32,297 are stationed in tropical and subtropical regions. When Porto Rico was occupied after the war with Spain, it was found that the civilian population was ravaged with a disease known as "tropical anemia"; the work of Colonel Ashford and others shewed that this was ankylostomiasis, and the island was now not merely healthy but exceedingly flourishing. In the Philippine Islands a board for the investigation of tropical diseases was instituted in 1900 and functioned till 1915; it was under the ægis of this board that Strong made his study of bacillary dysentery in Manila, that Craig and Ashburn demonstrated the rôle of *Stegomyia* in transmitting dengue, that Vedder carried out his work on beriberi and amœbic dysentery; whilst in 1922 there was created the U. S. A. Army Medical Department Research Board to carry forward the same duties. Studies in metabolism in the tropics, the incidence of intestinal parasitic infections and the epidemiology of dengue at present occupy their attention. Malaria is a problem requiring ever constant attention in the Panama Canal zone. Dengue is a disease which causes much sickness and is especially spread in the Southern States by automobile travellers; in 1923 it accounted for an admission rate of 79 per mille of American soldiers in the Philippines. The men of the army usually remain for but a short time in the tropics, the term of tropical service being 3 years in Panama and 2 years in the Philippines; and extended observations are now in progress to determine the effect of residence in a tropical climate upon their mental and physical efficiency.

General.—Dr. J. Azurdia next invited the members of the conference to visit Guatemala and commented on the difficulties of introducing efficient sanitation into the Central American States where the population consisted of Spaniards, Europeans, Negroes, Mestizos and the offsprings of these different races intermixed in different degrees, but most of them animated by the policy of "manana" (to-morrow, not to-day). The original Maya race in Central America had a high development of civilization, but there was but little trace of it to-day. Something of their skill with indigenous drugs must have been handed down through the generations, but from fear of the Spanish conquerors most of it had been concealed and lost. To-day which all races contributed during the great war, humanity is earnestly seeking a solution to prevent such catastrophes in future, and striving energetically towards an era of universal peace." But there can never be uninterrupted productive work, wealth and capital unless healthy conditions are produced, and preventive medicine is the basis for all future progress in the tropics.

Drs. H. C. Clark and J. Zetek read a paper on tick biting experiments in bovine and cervine piroplasmosis. The ticks *Margaropus annulatus* and *Amblyomma cayenense* are both found attached to cattle and deer in Panama. Experiments were carried out with the first. White-tailed deer shot in the locality shewed scanty *Piroplasma* infection. In one instance the

progeny of ticks removed from a sick deer proved capable of producing a mild attack of piroplasmiasis in a half-breed non-immune calf. Probably bovine and cervine piroplasmiasis in the district are identical, or else the tick in question is a carrier for two types of piroplasmiasis. The deer may, in fact, act as a reservoir for cattle piroplasmiasis in Panama. Dr. J. Iturbe also contributed a paper on the treatment of "derrengadera," a disease of cattle and horses due to *Trypanosoma venezuelense*, with "Bayer 205." There are two types of equine trypanosomiasis in Venezuela; "pesta boba," an acute disease with high fever and acute anæmia, terminating fatally in 80 per cent. of cases in from 15 to 60 days, and "derrengadera," characterised by the slow onset of paralytic symptoms, and with a 100 per cent. mortality. The disease differs from maldécaderas, due to *T. equinum*, in the absence of hæmoglobinuria, whilst the two trypanosomes are morphologically different. In the guinea-pig the trypanosome causes death from generalised œdema and hæmorrhage in 15 to 22 days; in a horse experimentally inoculated death supervened in about two months. The transmitting host is probably *Tabanus importunus*. Bayer 205 has proved an invaluable agent in the cure of the disease.

Finally Mr. W. H. Pickering read a paper on "What we know about Hurricanes," and Dr. W. E. Deeks one on the development of the medical department of the United Fruit Company.

* * * * *

We have devoted considerable space to a review of this wonderful and comprehensive work, but we trust that we have done so in the interests of our readers. We consider that since the publication of Byam and Archibald's "Practice of Medicine in the Tropics" there has been no other publication of equal importance to the present volume, which forms an admirable supplement and sequel to that larger work. We regret that no official delegate from India was present at the conference,—with the exception of Sir Leonard Rogers, who attended unofficially. The problems of tropical medicine are world-wide and international. That they are being very seriously considered and dealt with in Central America and the West Indies is evident; it appears to be India's role to make the discoveries and then to let the opportunities for applying them slide.

Current Topics.

Malarial Survey of the Mining Settlements of Singhbhum.

REPORT NO. 11.

By R. C. WATTS, M.D., D.P.H., D.T.M.,

CAPTAIN, I.M.S.,

From:—The Superintendent, Government Printing,
Bihar and Orissa, Patna.

THIS well-drafted and fully illustrated report is in continuation of the earlier preliminary report by Colonel Christophers, noticed in our issue for March 1924, and is interesting as shewing the different anti-malarial measures which may have to be adopted in different stations within the same district. In general Singhbhum is a tract of some 4,000 square miles, one quarter of which is covered by jungle. Taken as a whole it is a hilly upland tract containing hills alternating with valleys, steep jungle-clad mountains, and in the river-basins stretches of comparatively level or undulating country. On the whole the climate is hot and dry, though some 50 to 60 inches of rain fall during the monsoon period. The indigenous population are

aboriginies, and most of the labour for the mines has to be imported from Bengal or Madras. In order to irrigate their fields the local inhabitants do not use the large rivers or streams to any extent, but rely on "bunds," constructed to dam up nullah beds and thus create small reservoirs for drinking, bathing and irrigation. This damming of small streams leads to the presence of surface springs especially by the sides of rice fields, which become noteworthy and notorious sites for mosquito breeding. The country is one where malaria is hyper-endemic, and constitutes the most serious problem facing the mining industry.

Part I of the report deals with the mining settlements of the Bengal Iron Co. at Manoharpur, Duia and Chiria. At Manoharpur malaria is prevalent the whole year round, and in 1923 accounted for 2,205 out of 4,617 admissions to hospital. Here the mining settlement is situated on level ground cut up by the beds of various streams and rivulets. At Duia the camp is situated in a small valley, divided into two halves by a hilly ridge and surrounded on all sides by steep forest-clad hills, and the water-supply is from wells and the Duia stream. At Chiria the camp is situated at the foot of Buda hill and follows the river Hamsada. The total labour strength at the three camps is about 1,500. The chief anophelines present are *A. culicifacies*, *A. listoni*, *A. fuliginosus*, *A. rossi*, *A. willmori*, *A. jeyaporensis*, *A. foveoleri*, and *A. sinensis* (a fairly formidable but not complete list). The first is the most important carrier in the district, however. At Manoharpur the chief breeding sites were found to be the pools in the beds of three ravines, rice fields and the pools of subsoil water close to them, and pools in the bed of a large excavation made for the railway. At Duia the chief sites were pools in the bed of the main stream, also in the hospital nullah, but no larvæ were discovered in the wells. In footmarks, hoofmarks and spill water pools beside a spring half a mile from the Company's railway station, also anopheles larvæ were found swarming throughout the year. In Chiria the breeding places are extensive and numerous; the stony bed of the Hamsada stream, its tributary nullahs, swampy areas near the railway line, seepage water at the foot of Buda hill, and a cement masonry tank on the top of the hill all provide sites. The spleen rates at the three camps during the malarial season were 81 per cent., 57 per cent. and 67 per cent. On the other hand, Chiria shewed the highest endemic index and also the highest average number of parasites per c.mm. of blood, 1,485 as against 560 at Manoharpur.

Turning to anti-malarial measures, it is obviously impossible to eradicate malaria in the three camps; all that can be done is to try and keep it under control. Nor is it practicable to remove the sites of the camps. At Manoharpur the measures proposed are subsoil drainage for the Manoharpur ravine, purchase of one special rice field which is a pestilential source of anophelines and its drainage, and to either canalise or fill up the large excavation made by the railway. At Duia subsoil drainage for the hospital nullah is necessary. At both camps Capt. Watts suggests the best sites for future extensions and new bungalows and lines. At Chiria the present site cannot be effectively dealt with. Here the camp should be moved, either to the top of Buda hill, 2,700 feet, or to high, dry ground to the north-west of the present lines, when it could be supplied with a piped water-supply from the top of the hill. Turning to general measures, the present bungalows are not suitably constructed for screening, but a mosquito room, 10 ft. × 8 ft. × 8 ft. should be used in the evenings. An experiment at the foot of Buda hill shewed that subsoil drainage was the most practical way of dealing with rice fields and subsoil springs, whilst it proved practicable to oil wells without those using them having detected it. Local species of fish were found to be of no use as feeders on larvæ. Prophylactic quinine is suggestive as an additional measure. Finally, propaganda and education are essential.

Part II of the report deals with the Cape Copper Co.'s mines at Rakha, the North Anantapur gold mines at Chapri and Kandadih, and the Cordova Copper Co.'s mine at Mosaboni. At Rakha malaria is responsible for some 28 per cent. of the total sickness; the spleen rate was 44 per cent., and parasite infections up to 46,816 per c.mm. of blood were encountered, with an endemic index of 52.5 per cent. Again *A. culicifacies* was found to be the most important local carrier. The chief breeding sites were found to the Gurra river above its junction with the Kusumbagan stream and a *kutchra* tank and paddy fields in the centre of the camp. It is recommended that the tank should be abolished, and the paddy field purchased and drained; that the discharge from the main shaft, containing copper sulphate solution, should be discharged into the Gurra river further upstream in order to kill the larvæ, and that the areas surrounding wells should be dealt with. The mine agent's bungalow is too near the village and should not be occupied for residential purposes; but if it is not possible to leave it, it should be screened. At Chapri and Kandadih, two villages a mile apart, there were 638 admissions for malaria out of a total labour force of 1,441 between August and October, 1923. The spleen rates were 64 per cent. and 34 per cent. respectively, and the endemic indices 43 per cent. and 36 per cent. *A. culicifacies* here again was the most important local carrier. Both camps are too near the local villages and should be moved. At Kandadih suitable high, dry land is available, and as both camps are still temporary their removal to better sites is indicated. At Mosaboni about 100 out of the 735 coolies go sick with malaria monthly and the spleen index was 33 per cent. Here the predominant mosquito was *A. rossi* and not *A. culicifacies*, the latter being found only in two nullahs and in Mosaboni tank. This area requires re-survey during the malarial season.

In Part III, Capt. Watts deals with certain clinical observations made during the survey. Of 242 control adults examined, the average hæmoglobin percentage was 80. Among children at Manoharpur, Duia and Chiria the index in November 1923 was 75 per cent. in children 1 to 5 years of age, 76 per cent. in children 6 to 10 years of age, and 80 per cent. in children 11 to 15 years of age; for April 1924, during the non-malarial season the corresponding figures were 93, 97 and 98 per cent. Amongst immigrant children at Rakha 33 per cent. became infected within the first year of residence at ages 0 to 5 years, and it is interesting to note that the average splenic enlargement was more than double that among the aborigines of the locality. Conditions among adult immigrants entering the area are very bad; of the labour force constructing the Amda-Jamda railway the engineer in charge estimated the loss of efficiency from malaria to be 50 per cent., and every man discharged had to be given three months' leave to recuperate his health. At one mine 300 Madras labourers were imported; within a fortnight 10 of them had died of cerebral malaria and the rest had to leave the area owing to being constantly fever-stricken. The spleen rate amongst adult immigrants is double that for the aboriginal population and the average number of parasites per c.mm. about four times that for the local population. The majority of parasites encountered resembled the "*Plasmodium tenue*" of Stephens.

In summarising the measures necessary, Capt. Watts comments on the necessity for such commercial undertakings to consult expert medical opinion as to selection of camp sites; if this is not done, sites near nullahs which are pestilential mosquito breeding grounds may be selected; the coolie will live near water if he can, whereas the high, dry ground is better, and jungle should be cleared for at least 200 yards around the camp site. Wet rice cultivation is the second danger and no buildings should be constructed within quarter of a mile of such fields. Susceptible persons should be housed in quarters some distance away from the local villagers, whilst if prophylactic quinine is issued it should be given

under supervision, 10 grains on two consecutive days a week. Finally, he lays down the duties and uses of mosquito brigades, which should be under a supervisor of the Maharaj class, whom the coolies will respect owing to his caste.

"The British Journal of Venereal Diseases."*

THE study of venereal diseases has passed through various stages; in the remote past the subject was often regarded as somewhat taboo; to-day it is discussed, even by laymen, with a frankness which would have horrified our grandmothers; it even forms the plot of such popular novels as "*The Green Hat*." From the medical point of view syphilis has been classed first with urology, then with dermatology; whereas in reality it forms a very important part of all general medicine. With the introduction of salvarsan and its derivatives, of the Wassermann test, and of self-disinfection, the whole attitude of the medical profession towards venereal diseases has altered; and the subject is one of enormous importance. The appearance therefore of *The British Journal of Venereal Diseases*, a new quarterly publication, is fully justified. It is intended to deal in each issue with two of the following subjects, reviewing the recent literature:—syphilis, gonorrhœa, the pathology and biochemistry of venereal diseases, neurology in relation to venereal diseases, dermatology in relation to venereal diseases, pediatrics and gynecology in the same relationship, urology and sociology in the same relationship. Thus the journal will have a very wide field of interest and should appeal to several different classes of medical men.

In the first number Colonel L. W. Harrison deals with the public health organisation in England and Wales to combat venereal diseases. Here the main lines of policy followed since 1918 have been the setting up of gratuitous treatment centres, the extensive provision of facilities for free laboratory examinations and tests, free supply of arsenobenzol compounds, and the education of the public. The total attendance at these centres in England and Wales in 1923 was no less than 1,605,617; and Colonel Harrison concludes that there has been a real decline in the incidence of syphilis in the general population. With regard to gonorrhœa, however, matters are more difficult. This is largely due to the lightness with which the public regards this disease; but it is also largely due to its indifferent treatment by medical men. In reality to-day gonorrhœa is more difficult to diagnose and treat properly than is syphilis, whilst its incidence is at least from 2½ to 3 times that of syphilis. The chronic gonococcus carrier is one of the gravest menaces to public health; and in Colonel Harrison's opinion this is a matter where full and adequate hospital facilities to ensure complete and absolute sterilisation of the infection should be provided, since it is very difficult for the ordinary medical practitioner to carry out treatment to this stage. Further, incessant education of the public is very necessary.

Drs. E. P. Cumberbatch and C. A. Robinson deal with the use of diathermy in gonococcal infection. The gonococcus is exceedingly susceptible to heat whilst a temperature of 114°F. can be reached in the cervix uteri by a diathermy apparatus; also in addition to its direct action on the gonococcus diathermy assists phagocytosis and increases tissue resistance. In the female these authors first apply diathermy to the urethra; a bougie electrode is inserted, and the circuit completed by a belt electrode of sheet lead secured around the pelvis. The current is gradually increased until the sensation of heat gives way to that of pain; it is then decreased until there is no pain and is kept at this strength for ten minutes. The cervix is next treated; here the cervix is insensitive, but the previous application to the urethra will have determined the current

* *The British Journal of Venereal Diseases*. Published by the Oxford University Press and Messrs. Constable and Co., London; and P. O. Box No. 31, Bombay. Price 20s. annually; 6s. per number.

necessary to produce a temperature of 114°F., and this is applied for ten minutes. Where a vaginal speculum cannot be applied, as in children suffering from gonococcal urethritis, diathermy can still be applied by the rectal route.

Dr. W. J. Tulloch writes on the complement-fixation reaction in gonorrhoea. Here it is essential first that the antigen used must be devoid of anti-complementary qualities, since the humoral response in the disease is slight; secondly, to use a strain which has been proved by absorption of agglutinins to belong to the predominant type. The technique is described in full detail and the author comes to the following conclusions:—(1) That sera giving a positive Wassermann reaction do not give false positive reactions in the gonococcus fixation test, the figures shewing a maximum probable error of only 2.6 per cent. (2) That the test appears to give markedly specific results; in 30 out of 561 cases, a positive fixation test was followed by negative microscopical findings; but all 30 cases were females and the presumption of gonorrhoea was strong in all; the error in any case does not exceed 6 per cent. (3) That the test is one of considerable delicacy.

Dr. F. T. Burke reviews the present position of bismuth therapy in syphilis. He places the relative values of the "anti-syphilitic triad" as follows:—arsenic, 10; bismuth, 8; mercury 3. Bismostab, which consists of finely divided metallic bismuth suspended in a 5 per cent. glucose solution, is advocated and deep injection into the gluteus. The following is his routine treatment for a case of syphilis seen in the early primary state:—

Stabilarsan once weekly for	..	8 weeks
Bismostab thrice weekly for	..	4 weeks
Stabilarsan once weekly for	..	8 weeks
Bismostab thrice weekly for	..	4 weeks,

being a total course of 24 weeks. He summarises the present position with regard to bismuth as follows:—

"Bismuth is a most valuable and powerful drug in the therapy of syphilis, in all stages of the disease. It falls very little short of arsenobenzol in its effect upon the superficial and visceral manifestations, and upon the serological reactions of the blood and cerebro-spinal fluid. Unlike arsenic, its use does not expose the patient to any serious risk; no fatality from its use has been recorded. Having a tremendously higher therapeutic value than mercury, the amount of treatment now required is correspondingly decreased. With bismuth, modern and rapid treatment can be administered to the arsenic-intolerant patient which until its introduction was impossible. Bismuth provides a means of dealing adequately with the Wassermann-fast patient and of securing a permanent negative.

There can be no question but that metallic bismuth is the preparation of choice, not only from the point of view of avoiding toxic effects, but also on account of the mode of action of the element within the body. Finally, emphasis cannot be laid too strongly upon the absolute necessity which exists for a good technique in administration if one would avoid pain, discomfort, and the danger of injecting into the blood-stream."

Dr. S. Lomholt writes on the pharmacology of bismuth; the rate of absorption is a very important point, and watery solutions must be preferred to oily ones for practical use. He prefers the hydroxide, with glycerine added to ensure homogeneous suspension; 12 grammes of basic bismuth nitrate are dissolved in dilute nitric acid. A surplus of ammonia is then added, resulting in a fine precipitate of bismuth hydroxide. This precipitate is next very carefully washed, preferably under aspiration; then 10 c.c. of pure glycerine and 40 c.c. of sterile water are added and the suspension is ready for use; the dosage being 1 c.c. or about 20 c.m. once a week. This preparation is very cheap and suitable for use on a big scale, as it costs less than an anna for a dose of 0.2 gm.

Dr. R. N. Ironside writes on the treatment of general paralysis by malarial inoculation. This line of

treatment is not the wonderful one that many continental writers think it is, but it is a useful measure. Success depends upon choosing early cases free from arterial disease and bronchial infection; and the treatment should be withheld from all debilitated paretics and from all patients over 50 years of age. The method of inoculation giving most satisfactory results is by infection by mosquitoes.

A useful article follows by Dr. H. C. Semon on skin affections commonly mistaken for syphilis, an article which should be read in the original. There is perhaps no commoner mistake in medical practice in this country than to mistake psoriasis, tinea and even seborrhoeic dermatitis for a syphilide and send the patient for a Wassermann reaction test.

It will be seen that *The British Journal of Venereal Diseases* is a journal full of interest to the clinician and laboratory worker alike.

Vitamin-Content of the Banana.

(*The Medical Review*, March 1925, p. 73.)

EVA SOPP (*Norsk Mag. f. Lægevidenskab*, p. 732) says that the banana is in many respects an ideal food. It is easily digested and it contains from 19 to 20 per cent. of sugar and starch, from 4 to 5 per cent. of protein, and from 0.5 to 1 per cent. of fat. Various investigators have found that there are large quantities of C vitamins and a certain amount of B vitamins in it. But there is a conflict of evidence over the existence of A vitamins. To clear up this point about 25 young rats, each weighing from 30 to 40 grams, were fed on an A vitamin-free basal diet until they began to show signs of A vitamin deficiency, and most of them had developed advanced xerophthalmia. The rats were then grouped in 3 classes, to each of which a different banana ration was given. The banana was eaten with avidity, and it was found that the first group of rats, to whom an unlimited supply of banana had been given, showed little improvement during the first fortnight. But afterwards rapid improvement was observed, and when the experiment was completed after 10 to 12 weeks, the rats were well developed, and most of them had completely recovered from the ill-effects of the A vitamin-free diet. Another group of rats was given 2 gm. of banana daily, per rat. The rats in the remaining group were each given only 1 gm. of banana daily, in addition to the basal A vitamin-free diet, and it was anticipated that this supply of banana would be inadequate to combat the effects of severe A vitamin deficiency. But the rats in this group thrived practically as well as did those in the first group. The writer concludes that the banana contains vitamins capable of preventing and curing diseases due to A vitamin deficiency, and that, to a less extent, or at any rate more slowly, the vitamins in the banana promote growth. Applying these observations to human beings, she points out that 1 gm. of banana a day is to a 50-gram rat as 4 or 5 bananas are to a 3-year old child. But it is probable that this weight for weight comparison is misleading, and that considerably less than 4 or 5 bananas a day should be sufficient to provide a 3-year old child with enough A vitamins.

Reviews.

THE MEDICAL ANNUAL: A Year Book of Treatment and Practitioner's Index, 1925. Bristol: John Wright & Sons, Ltd. Pp. 608. Price, 20s. net.

THIS is the forty-third volume of a yearly publication which most medical men regard as indispensable. The high standard of the previous issues has been fully maintained and the Medical Annual continues to supply the medical man with a critical digest of all the most important work of the proceeding year.

Aug., 1925.]

The contributors, twenty-eight in number, are recognized authorities on the subjects with which they deal so that the contents are far from being mere abstracts, they represent real contributions to medical science culled and critically presented by experts.

Medical men in India and in the tropics generally are specially favoured, the most important tropical diseases are dealt with by Sir Leonard Rogers, and eye diseases by Lieutenant-Colonel Lister.

The sections on eye diseases are remarkably complete and instructive, an exceptionally interesting section is that on the slit lamp microscopy of the living eye with two coloured plates from the book of Prof. Vogt. In the other sections on eye diseases, the author gives us the benefit of his ripe experience of ophthalmology in India and Europe.

The contributors and publishers continue to earn the hearty gratitude of all English reading medical men, especially those who have to work in isolation.

A complete annual course of post-graduate instruction at a cost of twenty shillings is brought within the reach of all.

Altogether the book is indispensable for all medical men who desire to give their patients the benefit of the recent discoveries of medical scientists.

SEWAGE DISPOSAL IN INDIA AND THE EAST.—

By George Bransby Williams, M.I.C.E., F.R.S.I., F.R.C.S., Chief Engineer, Public Health Department, Bengal. Calcutta and Simla: Thacker, Spink & Co., 1924. Pp. 230, with 52 illustrations. Price, Rs. 10-8.

THIS is the most important treatise on the treatment and disposal of sewage in the East since Fowler and Clemesha's report on the working of septic tanks in Bengal and Clemesha's "Sewage Disposal in the Tropics." These, however, dealt with the problem in a very specialised and restricted manner and were largely a result of the work done by these experts on septic tank latrines in Bengal which they did so much to develop. The present book, however, is much more ambitious and surveys the subject in a wide comprehensive manner. Sewage is sewage all the world over and the problem of its disposal is everywhere essentially the same—it has to be converted into stable inoffensive bodies devoid of danger to the community by means which should be at once suitable, rapid, devoid of nuisance and economical. The principles remain the same but their application must vary with the composition of the material to be dealt with, the climate, the local geographical conditions, etc., and the amount of money available. It is on account of these differences that the methods of sewage disposal in India must vary as compared with European and American methods not only generally but in particular localities though the principles remain the same. The wide experience of the author of European, African and Indian conditions is evident throughout the book.

The principles of sewage treatment are firstly clearly enunciated, then the differences between domestic sewage in European, American and Indian communities are discussed; the development of scientific methods explained and clear descriptions of actual works in India and elsewhere given. Perhaps the most interesting chapter of the book is on sewage irrigation—a full description of the sewage outfall works at Dacca designed and carried out by the author is given. The preliminary experiments and the results of cultivation as shown by the table on p. 108 and the accompanying illustrations look almost too good to be true; as much as 120,000 gallons per acre per day being applied for a month at a time without sewage sickness or ponding. Such results on Bengal alluvial soil are distinctly encouraging and it is hoped that the sanguine optimism expressed will be fulfilled. The activated sludge process is clearly described and the illustrations of the installation at the Bengal Engineering College at Sibpur make the process quite clear. A very important chapter is the one dealing with sludge disposal which may be said to be the bugbear of every sanitary engineer.

The author is of opinion that the system of sedimentation and land irrigation combined with air drying of the sludge during the dry weather and sludge digestion during the rains (after the methods of Watson of Birmingham and as carried out at Pretoria) may prove a satisfactory solution of the Indian sewage disposal problem and the Tittagar Sewage Works which are now under construction have been designed on this principle. The installation at Dacca and at Tittagar will be followed with great interest by many interested persons both of the engineering and medical professions and it is hoped that Mr. Bransby Williams will from time to time publish the results obtained from these disposal works. Especially valuable is the final chapter on "general considerations" where the important factor of finance is considered. A table is given of the amount spent by various municipalities in Bengal on conservancy and maintenance of drains. This averages over one rupee per head of population, Howrah leading with Rs. 2-11-0 per head. The majority of these towns have a hand and cart removal system with trenching. In a town like Howrah, with nearly 200,000 inhabitants the amount of daily labour and daily nuisance can be imagined and this at a cost of 4 lakhs of rupees per annum. Mr. Williams shows that it is very unlikely that any Bengal Municipality would be able to finance a water-borne sewage system with the ordinary available revenue, but points out that the saving in sickness rate would go a long way towards making up the deficit. But it is difficult to get a primitive people to break away from Nature and to break the various vicious circles which result from too close a contact between human beings and human excreta, circles which are the cause of so many diseases in tropical countries—hookworm, enteric, cholera and dysentery. The book will be appreciated by the large number of interested people in India and will add to the author's already high reputation as a sanitary engineer. It is well bound and the numerous illustrations which are well reproduced add considerably to its value.

OPERATIVE SURGERY.—By Warren Stone Blackham, M.D., F.A.C.S., formerly Surgeon, Manhattan State Hospital, New York; and Instructor in Operative Surgery, College of Physicians and Surgeons, Columbia University. In six volumes. Philadelphia and London: W. B. Saunders Co. Vol. V., pp. 880; Vol. VI., pp. 980. Price, 50s. net per volume, also free Index volume, pp. 189.

THESE two volumes complete this enormous work on operative surgery. In the reviews of the previous volumes we have expressed our opinion on the scope and character of the work in general, so that beyond noticing the contents of the present volumes there is nothing to add to what we have already said. Volume V opens with the operations upon the colo-recto-anal tract and so completes the section on the alimentary canal. All the well-known operations will be found here and the descriptions are as usual very full and admirably illustrated. We would suggest that an illustration of the arterial supply of the sigmoid and rectum would be helpful in making clear the importance of the correct placing of the ligatures in high excisions of the rectum. The minor rectal operations are illustrated by numerous figures all admirably clear. The descriptions of the methods of dealing with fissure in ano do not make clear the real object of the operation by incision, which is to obtain adequate drainage and not to paralyse the sphincter, the latter is neither necessary nor desirable. The rest of the volume deals with the surgery of the kidneys, ureter, bladder and male genitals. As usual, a very great number of methods is detailed, without much guidance to help the reader to choose the best, but this is the case with the whole work. No less than 16 methods of uretero-ureterostomy are described, but Peter's operation for exstrophy of the bladder by implantation of the ureters into the rectum, the best of all methods is not mentioned. Fig. 4677 is supposed to represent the technique of catheterization of the ureters, the cystoscope is so placed that the

prism looks directly upwards, at an angle at which it would appear impossible that the ureteric orifices would be visible, the usual method with the beak of the instrument pointing downwards is given us as an alternative technique, but it is the method universally used and the only method which need be described. On the whole, however, these chapters form a well-balanced series, the descriptions of urethral and bladder technique being particularly good.

Volume VI opens with the operations on the prostate and seminal vesicles, methods of prostatectomy being, of course, the longest section. The author's remarks on the merits of suprapubic and perineal prostatectomy are very cautious and we regret that he has not seen fit to give us the tabulation of the points for and against each operation which he had prepared, but found it so contradictory that he decided to omit it. The various methods of performing these operations are very well and carefully described, the descriptions of the perineal methods being much more detailed than is usual. Thomson Walker's operation is, we suppose, too recent to be included. The rest of this volume deals with gynaecological and obstetric operations, a department in which the reviewer does not feel competent to criticise; at the end are found some orthopedic operations which could not be classified under any of the previous sections. The index volume appears to be very complete. We have said before that we rank this work very high, it is a monument of industry and erudition of which the author may well be proud. That it does not make particularly interesting reading is a fault inherent in works of this character as well as in dictionaries and encyclopedias, it cannot be held to detract from their merits in their own sphere. The author set out to write a work of this character and he has succeeded admirably. Its proper place is on the shelves of a reference library and we recommend all medical libraries to purchase it.

ABT'S PEDIATRICS.—Vol. IV. Practical Medicine Series, 1924. Chicago: The Year Book Publishers. Pp. 381. Price, \$2.00.

We congratulate the Year Book Publishers, Chicago, on having produced this year one of those admirable practical medicine series devoted for the first time exclusively to pediatrics. Hitherto it has shared its pages with orthopedics, and the fact that this year it requires a separate volume is significant of the growing interest in children's diseases. The literature has increased both in quality and quantity, and this book selects all that is best in recent advances. The publishers are fortunate in having this volume edited again by the well-known pediatrician Dr. Abt whose criticisms are brief and pithy, characterised by a careful judgment, wise philosophy and delightful humour. Lest the young and enthusiastic general practitioner should swallow all that is new, the experienced editor adds a fair yet definite note of warning, e.g., when the value of the banana is extolled in the treatment of coeliac disease he tersely adds this comment:—"It may be good; time will tell."

The subject-matter is well arranged, starting with diseases of the newborn, feeding of infants and nutritional disorders, proceeding to infectious diseases and thence to diseases of the different systems, so that the busy practitioner can refer to any clinical condition quickly. Each subject treated is printed in bold type, the author's name stated, and the journal from which the summary was made given in a footnote so that the original article can be consulted.

We commend this volume to all as containing in brief the best collection of recent work in the department of pediatrics.

THE STATICS OF THE FEMALE PELVIC VISCERA, VOL. II.—By R. H. Paramore, M.D. (Lond.), F.R.C.S. (Eng.). London: H. K. Lewis & Co., Ltd., 1925. Pp. xx plus 424, with 58 illustrations. Price, 24s. net.

In volume II of "The Statics of the Female Pelvic Viscera," R. H. Paramore has advanced another step

towards the still unsolved puzzle of prolapse and as to how the viscera are normally retained in the pelvis. It is complementary to volume I, but it does not conclude with the mystery explained.

It shows a most methodical investigation of the problem, for the author surveys the whole history of the treatment of prolapse from 1742 to 1899. He has followed the evolutionary method tracing the developments in chronological order, yet his book is no mere description of antiquated procedures but a reasoned critical survey wherein he elucidates every advance in thought and in surgical performance and ascribes to each writer and operator due praise for any advance to the solution of the problem of pudendal hernia. The aim too is constructive—not to minimise the work of these pioneers but to seek out whatever in it was good and show how later operators have improved on older conceptions and procedures.

The first measures were necessarily experimental and therefore unscientific. In more recent decades the treatment has tended in two directions, a selection of cases and the employment of several different measures in concert.

The author shows a rare judgment in examining the results of these various surgical procedures, yet he does not consider operations alone but tries to get at the underlying ideas of prolapse which prompted these operations. His own idea, more hinted at than stated,—is that a difference in pressure obtaining about the body and cervix of the uterus in some corrected form is the idea which must prevail.

He strives to get away from indefiniteness in thought and inexactitude in terminology and suggests the name "pudendal hernia" as connoting the pathology.

He concludes that support from below and suspension from above for the cure of prolapse have failed and that it is due to a loss of equilibrium in the realm of abdomino-pelvic dynamics. We shall welcome volume III whether it shows us how to restore that equilibrium or not, for volume II is well written, well illustrated, well produced and a perusal of it will repay any gynaecologist before he proceeds to any radical operation for prolapse.

CHAVASSE'S ADVICE TO A MOTHER.—By G. T. Wrench, M.D., B.S. (Lond.). Nineteenth Edition. London: J. & A. Churchill. Pp. 346. Price, 2s. 6d. net.

THE publication of the 19th authorised edition of Dr. Chavasse's "Advice to a Mother" speaks well for the value and undiminished popularity of this eminently practical little volume. It has been revised by G. T. Wrench, past assistant-master of the Rotunda Hospital, Dublin, and it is written in a simple, breezy style calculated to captivate the attention of any mother anxious about the management of her children.

Like all Gaul it is divided into three parts sensibly treating the three stages in development, infancy, childhood and boyhood, and giving useful advice on feeding, teething, clothing, exercise and common ailments. The chapter on infant feeding has been re-written but we note the author does not believe in four-hourly feeds and in the early weeks allows one night feed. The other chapters have been brought up to date and embody the latest teaching. The care of children in the tropics is relegated to the concluding four pages so that there are many points on which the mother in India will search in vain for enlightenment. At the same time we commend the book to the mother in the *mofussil* as a useful source for reference in emergencies and for the treatment of minor illnesses.

ESSENTIALS OF INFANT FEEDING.—By E. A. Barton. London: H. K. Lewis & Co., Ltd., 1925. Pp. viii plus 80. Price, 3s. 6d. net.

E. A. BARTON in his "Essentials of Infant Feeding" presents the main outlines of this subject in an easily readable and easily assimilable little book of 80 pages. He writes for the average student not for the pediatrician, and he has succeeded in his aim of compressing

Aug., 1925.]

much valuable information into small compass and at small cost. The teaching is practical. The essential points in breast feeding, the constituents of cow's milk, the value of vitamins, the need for accuracy in artificial feeding are ably set forth in such a manner that their perusal will benefit alike the Indian student who wishes to profit by his attendance at any infant clinic and the Indian practitioner who finds to-day that he requires more knowledge of the important subject of infant feeding.

Annual Reports.

TRIENNIAL REPORT OF THE PATNA MENTAL HOSPITAL FOR THE YEARS 1921-23. BY LIEUTENANT-COLONEL H. R. DUTTON, I.M.S. PATNA: SUPERINTENDENT, GOVT. PRINTING, BIHAR AND ORISSA, 1924. PRICE, 14 ANNAS.

THIS hospital has accommodation for 275 male and 66 female patients, and the numbers treated varied from 316 in 1921 to 331 in 1923. The percentage discharged cured was 8.39. Improved dietaries and other prophylactic measures reduced the daily sick rate from 57.5 in 1921 to 39.56 in 1923. Thirty cases of tuberculosis were treated during the period, being segregated in an open ward and given systematic injections of sodium marrhuate, and Colonel Dutton speaks well of the results of such treatment. The admissions for dysentery rose from 20 in 1921 to 36 in 1923, chiefly owing to relapsing amoebic infections. An increase is also to be noted in ankylostomiasis, said to be due to patients of dirty habits eating garbage and earth. The average number of deaths was 23 as against 35 for the previous triennium. Criminal lunatics increased from 116 in 1921 to 122 in 1923.

The chief types of insanity dealt with were mania, melancholia, mental stupor, insanity due to *Cannabis indica* and alcohol, dementia praecox, imbecility and idiocy. The chief ætiological factors concerned were ganja, alcohol, toxic causes, critical periods of life and mental stress. The total cost of the mental hospital during the triennium was Rs. 1,80,065, and the average cost per patient per annum from Rs. 204 to Rs. 222, whilst there was an average annual profit of Rs. 2,410 from goods manufactured at the hospital. Diets were liberal, and the sanitary state of the hospital was good. The drinking water is chlorinated. The stools of all patients were examined, and those infected with intestinal parasites were systematically treated. Prophylactic quinine and thymol were also used.

THE SOUTH AFRICAN INSTITUTE FOR MEDICAL RESEARCH, JOHANNESBURGH. ANNUAL REPORT FOR 1923.

THE annual reports of this institute are always interesting reading; for, in addition to a large volume of routine work, there is also a considerable output of interesting research work, and the staff include such well-known workers as Dr. Watkins-Pitchford as Director, Sir F. Spencer Lister as bacteriologist, Dr. Annie Porter as parasitologist and Professor H. B. Fantham as honorary protozoologist. Among other general activities of the year was the preparation of an exhibit for the British Empire Exhibition at Wembley, illustrating "miner's phthisis," a further exhibit dealing with work in South Africa, and the preparation of a cinema film illustrating bilharzial life cycles and transmission.

On the research side, an outbreak of cerebro-spinal meningitis which occurred in July was investigated. Of 36 strains of the meningococcus from African or Indian patients, 25 belonged to Lister's group E, as

also did 10 out of 23 strains from European patients. Gordon's type 1 meningococcus, previously prevalent in the area, was almost absent in the outbreak. As a routine prophylactic against lobar pneumonia, all new arrivals at the mines are vaccinated three times with a pneumococcal vaccine, and in 1923 a dose of 1,000 million of Gordon's type 1 meningococcus was added to the pneumococcus vaccine. Whether this was partly responsible for the great diminution in the incidence of this strain, however, is problematical, since from 1920 to 1922 its incidence had fallen from 72 per cent. of all strains tested to 27 per cent. Of 18 strains of pneumococcus isolated from cerebro-spinal fluid obtained by lumbar puncture, no less than 15 did not correspond with any known group.

Considerable work was done on filter-passing organisms isolated from (a) cases of epidemic influenza, and (b) cases of African horse-sickness. The former was reported on by Dr. Olitsky to be identical with the strain isolated there; the latter appear to belong to the same group as *Bacterium pneumosintes*, the filterable virus supposed to be the cause of epidemic influenza. Animals inoculated with the isolated virus developed symptoms typical of horse-sickness, but there appeared to be but little evidence of subsequent immunity.

An informal conference was held on the whole question of regulations with regard to meat-producing industries. It was decided that if a carcass shewed not more than ten cysticerci, and if these were not widely distributed, the infected part should be excised, and the parts not affected passed as fit for consumption after being kept at a temperature not higher than 10°C., for at least twelve weeks.

Several massive infestations with *Ascaris lumbricoides* have been encountered at Johannesburg, including four cases of intestinal obstruction, from one of which 851 worms were removed at operation. One of the four cases proved fatal from gangrene of the jejunum and perforation. In connection with schistosomiasis, two or perhaps three potential hosts of *S. haematobium* have been found among snails of the genus *Isidora*.

In connection with miner's silicosis it was found that guinea-pigs which had inhaled phthisis-producing dust, after either intraperitoneal inoculation with tubercle bacilli, or intratracheal inoculation with pathogenic cocci, developed a condition of the lungs similar to that met with in miner's phthisis. In the majority of cases of miner's phthisis, the condition present is really a silico-tuberculosis, the tubercular infection being grafted on to a pre-existing silicosis. Experiments are in progress to determine the best methods of ventilation, cooling and dust control.

TRIENNIAL REPORT OF THE MENTAL HOSPITALS IN BENGAL FOR THE YEARS 1921-1923. BY MAJOR-GENERAL R. HEARD, C.I.E., K.H.S., M.D., I.M.S. CALCUTTA: BENGAL SECRETARIAT BOOK DEPOT, 1924. PRICE, RS. 3.

ONE of the notable events of the triennium was the change in nomenclature from "lunatic asylums" to "mental hospitals," a change which indicates a new policy with reference to mental patients, who are in the majority of instances capable of cure or improvement. The institutions at work during the triennium were the mental hospitals at Berhampore and Dacca, the observation ward at Bhowanipore, and the ward for insane lepers at Gobra, the accommodation in which is for 764, 343, 4 and 10 patients respectively. The annual average number of patients was 1,215, and 41 paying private patients were admitted during the period. An average number of 102 patients a year were discharged cured. One escape of a criminal lunatic occurred in 1923 from the Berhampore hospital, but the patient was subsequently run over by a train.

The daily average number of sick was 118, malaria being the disease chiefly responsible; dysentery was

epidemic in the Berhampore hospital in 1923 and a segregation ward had to be opened. There was a recrudescence of influenza in 1921, whilst tuberculosis was also prevalent. The deaths averaged 70 per annum as against 102 per annum in the previous triennium. Of the types of insanity dealt with mania was the commonest, whilst 320 patients were admitted suffering from the effects of *Cannabis indica*. The superintendents of the hospitals complain that very little attention is paid by committing authorities to furnishing the necessary information with regard to patients sent in. The average annual income amounted to Rs. 2,98,483 as against an annual average expenditure of Rs. 3,17,925, the chief item of increase being the opening of the new observation ward at Bhowanipore. Profits from manufactures varied from Rs. 8,438 to Rs. 14,124 per annum. Dietaries were improved, especially at Dacca, where there was an ample supply of vegetables from the hospital garden and an issue of fish or meat on alternate days. At the Berhampore hospital a reading room and club for patients were opened, also an amusement fund, supported by public subscriptions. Considerable structural improvements were effected at the Berhampore Hospital, whilst a change in administration authorised the superintendent of the observation ward at Bhowanipore to become a certifying officer. In 1918 all European patients at Bhowanipore and Berhampore were transferred to the mental hospital at Ranchi; an Indian mental hospital is now in course of construction also at Ranchi, and it is hoped in 1925 to transfer to this hospital all Indian patients from both the Berhampore and Dacca hospitals.

Correspondence.

DIABETES AND INSULIN TREATMENT IN BENGAL.

To the Editor, "INDIAN MEDICAL GAZETTE."

SIR,—In the June issue of your *Gazette* Dr. Lal Mohan Ghosal, Demonstrator of Physiology, Medical College, Calcutta, published a paper entitled "Diabetes and Insulin Treatment in Bengal" in which he has made some sweeping and unwarranted statements about insulin treatment in this country. He begins with the statement that "insulin treatment in diabetes has become a common practice but so far as my experience goes both from hospital and private cases, not much benefit has accrued from it." In another place he writes "but alas in India the results are far from what was expected, very few cases are known to have derived benefit from it—far from getting cured."

As my experience in this line of treatment in Bengal covering about 400 cases of diabetes of various grades of severity is entirely contrary to his conclusions, I write these few lines in order to show that the basis of Dr. Ghosal's conclusions is fundamentally defective and that therefore they are unjustifiable and unacceptable.

Having made the hasty and ill-founded statement that insulin treatment in Bengal is more or less useless, the writer proceeds to find the reason of his assertion. He doubts whether the diabetes in Bengal is due to any pancreatic defect at all and having according to his own statement found no direct means to determine the pancreatic defect he falls back upon Cammidge's method of stool analysis and Cammidge's reaction in urine as the best means of determining the degree of pancreatic defect. He evidently takes it for granted that "pancreatic deficiency" as evidenced by Cammidge's method of stool examination includes the deficiency of the internal secretion (insulin) of the pancreas as well. This is where the mistake lies which destroys the whole value of his observations.

I am sorry that space will not permit me to discuss the merits of the Cammidge reaction. I can only say that Cammidge's reaction in urine is not made use of

nowadays and I would support this statement by quoting the opinion of the famous Mayo clinic on the value of the test. It says:—"If knowledge of the clinical histories and other factors of the personal equation be eliminated, the end results, judged by Cammidge's own criteria, must be considered, as a means of diagnosing disease of the pancreas both valueless and misleading." The same conclusions have been arrived at by many other distinguished workers in regard to this test.

Cammidge's method of stool analysis is still done and is of use in determining the degree of deficiency of the external secretion of the pancreas. This according to Cammidge's own statement is as follows:—"... a negative or low trypsin index and a high percentage of unabsorbed fat including an excessive proportion of unsoaped fat and neutral fat, in the quantitative analysis points to deficiency of the external secretion of the pancreas." This test does not give us any idea as to the deficiency or otherwise of the internal secretion of the pancreas manufactured by its islet cells, with which we are mainly concerned in diabetes.

On the basis of this Cammidge's test on the stools and by the degree of "pancreatic deficiency" indicated thereby, Dr. Ghosal groups out his cases of diabetes, a procedure which is open to grave objection. This classification is as unsound as it is unscientific, because as I have already stated, pancreatic deficiency as determined by Cammidge's test does not help us in finding the degree of deficiency of the internal secretion which is universally accepted as the causal factor in true diabetes. Moreover, it has satisfactorily been proved long ago that even ligation of the pancreatic duct, making it impossible for any external secretion of the organ to reach the intestine, fails to bring about glycosuria so long as the islet cells remained healthy.

It is interesting to note that nowhere in the whole of Dr. Ghosal's paper is there any mention of the glucose tolerance test and only a passing reference has been made in respect to blood sugar. This gives us the most reliable information as to the degree of damage done to the islet cells of the pancreas and which may be taken as the direct means of determining pancreatic deficiency in its relation to diabetes.

In summing up I would lay stress on the following points:—

(1) That the degree of "pancreatic deficiency" which Dr. Ghosal endeavours to bring out by Cammidge's test is not the kind of pancreatic deficiency with which we are concerned in cases of true diabetes—it does not show us the degree of damage done to the islet cells.

(2) That there are direct means by which the degree of damage done to the islet cells could be determined, the best of which according to eminent authorities on the subject is the glucose tolerance test.

(3) Lastly, Dr. Ghosal's statement as to the futility of insulin treatment of diabetes in this country would not stand the test of impartial enquiry into the matter. So far as my experience goes, insulin is not only palliative but in suitable cases a curative agent as well. It may be stated that I have had under my care a good number of cases of diabetes—some of which have yielded completely and the rest were decidedly benefited by it.

The difficulty of insulin treatment, as I pointed out in a previous paper in your esteemed journal, lies in the selection of proper cases. If the cases are properly selected and the relation of the dosage of insulin to the carbo-hydrate intake of the patient strictly adhered to, the results that will follow, will, I am sure, make Dr. Ghosal change his present opinion about the efficacy of insulin in the treatment of diabetes mellitus.—Yours, etc.,

J. P. BOSE, M.B., F.C.S.,
Mitra Research Worker on Diabetes,
Calcutta School of Tropical Medicine
and Hygiene.

CALCUTTA,
3rd July 1925.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Lieutenant-Colonel S. R. Christophers, C.I.E., I.M.S., is appointed to officiate as Director, Central Research Institute, Kasauli, *vice* Lieutenant-Colonel W. F. Harvey, C.I.E., I.M.S., with effect from the date on which he assumes charge of his duties.

Lieutenant-Colonel C. A. Gill, I.M.S., Officiating Director of Public Health, Punjab, held charge of the current duties of the Office of Inspector-General of Civil Hospitals, Punjab, from 8th to 18th May 1925 in addition to his own duties.

Lieutenant-Colonel G. Tate, I.M.S., is appointed to officiate as Inspector-General of Civil Hospitals, Punjab with effect from the 19th May 1925 and until the return from leave of Colonel Bakhle.

The services of Major E. E. Doyle, D.S.O., I.M.S., are placed permanently at the disposal of the Government of Bombay, with effect from the 27th March 1925, for employment in the Jail Department.

In supersession of the orders already issued, the services of Captain C. de C. Martin, M.B., I.M.S., an officer of the Medical Research Department, are placed temporarily at the disposal of the Government of Burma for appointment as Officiating Assistant Director, Pasteur Institute, Rangoon, with effect from the date on which he assumes charge of his duties.

Captain A. S. Fry, F.R.C.S.E., I.M.S., is appointed to officiate as Civil Surgeon, Simla (East), *vice* Lieutenant-Colonel J. M. A. Macmillan, with effect from the 12th May 1925.

The services of Captain Jamal-ud-Din, M.B., I.M.S., are placed temporarily at the disposal of the Government of the Punjab, with effect from the date on which he assumes charge of his duties.

LEAVE.

Colonel C. R. Bakhle, I.M.S., Inspector-General of Civil Hospitals, Punjab, is granted leave on average pay for 4 months, including privilege leave for 5 days, with effect from the 8th May 1925.

Lieutenant-Colonel J. M. A. Macmillan, M.D., F.R.C.S., I.M.S., Civil Surgeon, Simla (East), is granted two months' leave on average pay, with effect from the 18th April 1925.

In modification of the orders already issued, Lieutenant-Colonel W. R. Battye, D.S.O., I.M.S., an Agency Surgeon, is granted leave on average pay for 3 months and 20 days combined with leave on half average pay for 2 months and 11 days, under the Fundamental Rules with effect from the 7th May 1925.

Lieutenant-Colonel J. B. D. Hunter, O.B.E., I.M.S., an Agency Surgeon, on return from leave, is posted as Legation Surgeon, Nepal, and *ex-officio* Assistant to the British Envoy at the Court of Nepal, with effect from the 18th May 1925.

Captain R. H. Malone, M.D., I.M.S., Acting Director, Bombay Bacteriological Laboratory, is granted leave on average pay for four months combined with furlough under military rules for two months and study leave for six months, with effect from the 20th June 1925 or subsequent date on which he avails himself of the leave.

PROMOTIONS.

The promotion to his present rank of Major M. L. C. Irvine, M.B., I.M.S., notified in Army Department Notification No. 225, dated the 10th February 1922, is antedated from the 29th January 1922 to 29th July 1921.

The promotion to his present rank of Major M. Purvis, M.B., I.M.S., notified in Army Department Notification No. 1306, dated the 4th August 1922, is antedated from 30th July 1922 to 30th January 1922.

The provisional promotion of Captain P. A. C. Davenport, I.M.S., to the rank of Captain as notified in Army

Department Notification No. 236, dated the 22nd February 1924, is confirmed subject to His Majesty's approval.

Lieutenant to be Captain (Provisional).

G. H. Fitzgerald. Dated 10th June 1924.

Lieutenant to be temporary Captain.

R. T. W. Stoney. Dated 21st January 1920.

RETIREMENTS.

Lieutenant-Colonel A. T. Gage, C.I.E., M.B. 13th May 1925.

Lieutenant-Colonel E. C. C. Maunsell, M.B. 26th March 1925.

Lieutenant-Colonel F. D. S. Fayrer. 8th April 1925.

Lieutenant-Colonel A. Leventon, C.I.E., F.R.C.S.I. 27th April 1925.

Major C. H. Cross, I.M.S., on account of ill-health, 5th April 1925.

Major J. A. Cruickshank, M.C., I.M.S. 21st April 1925.

Office of the Director-General, Indian Medical Service.

CIRCULAR No. 1-C.

Simla, the 30th April 1925.

Reference this office circular No. 1-C., dated the 11th July 1921. The High Commissioner for India and the Medical Adviser to the Secretary of State for India have again brought to notice irregularities in regard to the submission, for approval of courses of study prior to the commencement of such courses. It is pointed out that under Rule 5 of the Study Leave Rules (General) and Rule 7 of the Indian Medical Service Rules, an officer is required, when applying for study leave in India, to submit, in addition to the Audit Officer's certificate, particulars of the course or courses of study contemplated and any examinations which he proposes to undergo.

It not infrequently happens, particularly in cases where study leave alone has been granted, or where it is combined with a short period of ordinary leave, that an officer takes up a course immediately on arrival in the United Kingdom without prior reference to the High Commissioner's Office or India Office* apparently on the assumption, probably to some extent excusable, that such reference, in view of the fact that he has already submitted his programme in India, is unnecessary.

Further, although Rule 13 of the general and Rule 7 of the Indian Medical Service Study Leave Rules provide that particulars of the study leave should be furnished to the High Commissioner's Office or India Office this is on occasions not done, or if not omitted altogether, is delayed so long as to render it useless for purposes of the exercise of effective control by the High Commissioner's Office or India Office.

Either of these circumstances makes it difficult or even impossible for the High Commissioner's Office or India Office to perform its function or supervising from the beginning an officer's study programme.

It would also appear, from recent experience of cases where an application for study leave is deferred until after arrival in the United Kingdom that some officers are unaware of the rule that a course of study should receive the prior approval of the High Commissioner or India Office and instances have occurred of application for study leave and for allowance in respect of study already embarked upon or completed.

It should be brought to the notice of all Indian Medical Service Officers that it would facilitate matters if all officers, whether granted study leave in India or whether they apply for it in the United Kingdom, should

* For Officers in military.

submit their programme to the High Commissioner or India Office before embarking on them.

Attention is also invited to paragraph 10 of the Study Leave Rules under which in order to qualify for the grant of study leave or for the receipt of study allowance a definite course of study must be approved as suitable by the Director-General, Indian Medical Service or by the High Commissioner, or Medical Adviser to the Secretary of State—otherwise the study allowance will not be admissible.

R. CHARLES MACWATT,

Major-General,

Director-General, Indian Medical Service.

NOTES.

CONFERENCE ON THE PROBLEM OF VENEREAL DISEASES.

THE National Council for Combating Venereal Diseases has decided to organise an Imperial Social Hygiene Conference to be held at the British Empire Exhibition, Wembley, on October 5th, 6th, and 7th of the present year.

It may be remembered that an Imperial Social Hygiene Congress was held at Wembley in May 1924, and was attended by many representatives of Government Departments and Local Bodies in the United Kingdom, of charitable and other organisations and of the Overseas Dominions including India. Those who were privileged to be present on that occasion will not soon forget the deeply-interesting nature of the papers read and the discussions carried on. It was perhaps a drawback that in the few days at the disposal of the Congress a great variety of important subjects were touched on, of which time did not permit the full discussion. At the Conference which will be held during the coming October, it has been decided to limit the discussion to Overseas problems and to take these up more in detail and more especially from the point of view of the expert. This will make the Conference all the more valuable for members of the medical profession who will have the opportunity of learning the views held, and weighing the experience gained in other parts of the Empire, while at the same time contributing such facts as India can bring to the common storehouse of knowledge. One day of the Conference will be devoted to a consideration of the medical aspects of venereal diseases and to the latest methods of diagnosis and treatment.

The widespread prevalence of venereal diseases and their serious consequences both to the individual and to the race has been recognised by most nations during the last twenty years. Energetic measures are being taken to combat them especially in Australia, Canada and the United Kingdom, and these measures are being attended by a gratifying amount of success. In India, as many practitioners have testified, the diseases are also widespread, especially in the cities. Speaking at the Congress, Sir Gerald Giffard, as representing Madras, put the incidence of the diseases at 25 per cent. of the population, and other speakers placed it even higher. So far, no action has been taken in India to combat the scourge nor is there outside the medical profession any real knowledge of the seriousness of the situation and of the growing menace to the public health.

Those who are organising the Conference hope that many medical practitioners from India, and others whose experience fits them to speak with authority, will attend the meetings either as representatives of public bodies or as private individuals.

Copies of the Proceedings of the 1924 Congress, which gives a valuable synopsis of the recent advances

in dealing with venereal diseases in all parts of the Empire (price 6/4, post free) may be obtained from the Honorary Secretary of the National Council for Combating Venereal Diseases, 102, Dean Street, Oxford Street, London, from whom also more detailed information regarding the coming Conference may be obtained.

MESSRS. C. BAKER'S PRICE LIST OF MICROSCOPES AND ACCESSORIES.

THE catalogue recently issued by Messrs. C. Baker, 244, High Holborn, London, W. C., contains many interesting items. The "R. M. S." microscope with all fittings for ordinary and for dark ground work at £67-3-0 is a *model de luxe*; the "D. P. H. 1 a" model for ordinary bacteriological and hæmatological work at £45-2-6 is good value; whilst the "stand T. D." fitted for all ordinary laboratory and bacteriological work at £42-12-6 is a good student's microscope. The Greenough dissecting microscope is one with a well-deserved reputation and comfortable to work with. A new lens introduced by the firm is a $\frac{1}{4}$ th inch oil immersion objective of N. A. O. 95, a lens useful for all types of high power work and especially suitable for dark ground illumination. Many kinds of interesting illuminating apparatus are included in the list, and also apparatus for drawing, projection and microphotography. The catalogue is one which will interest laboratory workers and research students everywhere.

MESSRS. HICKS' THERMOMETERS.

MESSRS. JAMES J. HICKS, the manufacturers of Hicks' Clinical Thermometers, whose advertisement appears elsewhere in this issue, are perhaps the premier thermometer makers in the world.

The firm has a huge business founded upon sound workmanship, and each thermometer is tested by an expert before it leaves the factory. The Indian agents are Messrs. Allen and Hanburys, Ltd., Block E., Clive Buildings, Calcutta, who will be pleased to forward price lists on application.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE Editor, *The Indian Medical Gazette*, c/o Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "The Indian Medical Gazette," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to the *Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of the *Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

NOTES ON SOME METHODS FOR DIAGNOSIS OF HOOKWORM INFECTION AND FOR ESTIMATING THE EGG OUTPUT.

By ASA C. CHANDLER, M.S., Ph.D.,

(From the Hookworm Research Laboratory, Indian Jute Mills Association Endowment, Calcutta School of Tropical Medicine and Hygiene).

LANE (1923-24) has recently described a new method for diagnosis of hookworm infection by direct centrifugal flotation (designated in this article "D.C.F." method), which he recommends as being distinctly superior to any other method yet devised. In brief the method consists in (1) centrifuging a suspension of one gram of faeces in water; (2) mixing the sediment with about 18 c.c. of saturated salt solution and centrifuging again in a special tube with the surface of the fluid in contact with a cover-glass; (3) removing the cover-glass by a rapid upward pull in order to remove a large hanging drop; and (4) examining the drop by resting the cover by the corners on small plasticine cones on a slide drop-side down. The essential special apparatus consists of special centrifuge buckets provided with horns to prevent the cover-glass from slipping while centrifuging, special flat-bottomed tubes of appropriate size, and cover-glasses 0.5 mm. thick. There are a number of details which contribute to the success of the method, for which Lane's original papers should be consulted by anyone who is interested.

Lane bases his claims for the superiority of his method on two points:—(1) The fact that a larger proportion of the total number of eggs in a 1-gram sample of faeces can be brought to light quicker than by any other method, hence greater accuracy in the diagnosis of light infections; and (2) a very great saving in time and of eye strain on the part of the microscopist, since the area of examination is greatly reduced and the concentration of eggs is such that in most positive stools one glance in the microscope is sufficient to establish the diagnosis. Lane has also called attention to unexpected inaccuracies in the Stoll egg-counting technique for estimating the degree of infection by egg output, using direct centrifugal flotation as a control. In our laboratory we have been using a modification of Stoll's technique for making egg-counts, which we believe to be considerably more accurate than Stoll's method and to be reliable in giving a reasonably accurate indication of the egg output of an individual. It was of considerable interest, therefore, to test our egg-counting method against the D.C.F. method pushed to finality, i.e., repeated until no more eggs could be obtained, as a control, and also to compare the number of eggs obtained

from a single spin of the centrifuge in the D.C.F. method with the number of eggs obtained on a slide by the Kofoid and Barber (1918) technique which we had been using previously in our laboratory, and by the Willis (1921) method which is very popular elsewhere. It is necessary to state briefly the details of the technique we used in the case of each of the methods we compared.

Our test of the D.C.F. method, in the absence of apparatus which conforms exactly to Lane's recommendations, was not made under optimum conditions, and there is little doubt but that when the correct apparatus is obtained still better results can be expected as regards the percentage of eggs brought up by a single spin of the centrifuge. With the centrifuge available—in the absence of a tachometer for measuring its speed—we are not sure that the optimum speed for bringing up the maximum number of eggs and the minimum amount of debris has been obtained. Moreover, we have used tubes having an inside diameter of 10 mm. instead of 12.5 to 14 mm. and in consequence got a concentration of the suspension about 50 per cent. greater than that recommended by Lane as the optimum. For these reasons there has been more camouflage in some of the preparations than there should have been and a lower percentage of eggs obtained in the first spin.

Until we adopted the D.C.F. method for diagnosis, the Kofoid and Barber method of salt flotation and surface looping was the method which we considered the most effective and least troublesome, and we have used it with very satisfactory results. We have had no difficulty in diagnosing most positive stools within a few seconds of examination of the slide. For comparing this method with the D.C.F. method we made no special effort to get the best possible results but only such results as can be expected in routine work when the preparation of the slides is left in the hands of an assistant. The receptacles we use are small glass tumblers of about 35 to 40 c.c. capacity, 2.5 cm. in diameter at the bottom and 4 cm. at the top, and 5 cm. in depth. Approximately 1 gram of stool, estimated without weighing or measuring, is placed in the tumbler and is thoroughly mixed with saturated salt solution, a little at a time; the glass is then filled nearly to the top with the salt solution and the coarse floating material is forced below the surface by a thin disc of No. 9 steel wool. After an hour the surface film is looped off with a coarse iron-wire loop and the loopsful of fluid placed between grease-pencil marks on a 1-in. by 3-in. slide and examined. About 20 dips of the loop are required to cover the surface. We have found that better results are obtained by using a small quantity of stool and thoroughly mixing it with the salt solution than when a larger quantity is used and incompletely comminuted, since in the latter case the steel wool screen becomes clogged and does not permit the free passage of eggs to the surface. The table attached shows that,

although a sufficient number of eggs are obtained by this method to make a positive diagnosis easy in most cases, the percentage of the total number of eggs which is obtained in this manner is surprisingly small and frequently falls under 10 per cent.

Many workers have selected the somewhat simpler Willis method for diagnosis. Lane compared the results obtained by this method with the results by his D.C.F. method and found it unexpectedly inaccurate. A similar comparison has been made here. For the Willis method we used $\frac{1}{4}$ -oz. faeces tins having a depth of 9 mm. and a diameter of 32 mm. About $\frac{1}{2}$ gram of faeces was thoroughly stirred up with saturated salt solution, a little at a time, until the container was full. A 2-in. by 3-in. slide was then rested on the surface of the fluid, more fluid being added until the entire surface was in contact with the glass. The slide was left for from 15 to 20 minutes and then removed by a rapid upward lift and examined. The results obtained were strikingly irregular. In a few instances considerably more numerous eggs were obtained from $\frac{1}{2}$ gram of faeces in this way than from 1 gram by the Kofoid and Barber method, but in the great majority of cases fewer eggs have been obtained, in some instances only about 10 per cent. However, in only two cases of very light infections, where the total counts by the D.C.F. method were 8 and 4 respectively, did the Willis method give negative results when the Kofoid and Barber method was positive. The larger number of eggs and smaller quantity of debris which is ordinarily obtained by the Kofoid and Barber method indicates it as undoubtedly the better of the two.

In comparing the results of these two methods as compared with the D.C.F. method, as set out in the following table, it should be borne in mind that by the Kofoid and Barber technique the eggs are scattered over an area of about 1,000 sq. mm., by the Willis method over about 800 to 1,000 sq. mm., and by the D.C.F. method over an area of only about 100 sq. mm. Even this does not give a true picture of the comparative concentration of eggs by these methods, since, as Lane has shown, by slight manipulation most of the eggs on a cover-glass prepared by the D.C.F. method can be herded to near the centre of the drop and the concentration there becomes several times greater. In other words, with an equal number of eggs obtained by these two methods the concentration of the eggs is at least twenty times greater by the D.C.F. method. Furthermore, almost without exception, the number of eggs brought to light by a single spin in the D.C.F. method was greater than the number collected by the Kofoid and Barber method. The advantages of this greater concentration in very light infections are obvious, but, in my experience, in all cases which have as many as 400 or 500 eggs per gram the diagnosis can be made very rapidly by the Kofoid and Barber method, often

by a single glance in the microscope. In this case there is no real advantage in the greater concentration of the eggs. It is in the case of negative stools that time and energy are saved, for here the saving in area to be examined is fully effective, and ten negatives can be passed by the D.C.F. method while one is being passed by the Kofoid and Barber method.

The striking difference in the results obtained by the D.C.F. method from different stools is interesting. In some instances, even without the optimum conditions, over 90 per cent. of all the eggs were obtained on the first spin, whereas in other cases less than 20 per cent. were recovered by the first spin under exactly similar conditions. No. 36 was especially peculiar in that eight spins were necessary to recover 160 eggs, the numbers obtained on each spin being as follows:—31, 33, 21, 34, 15, 11, 11, and 4; the pour-off was negative. It is also peculiar that the Kofoid and Barber method produced only 12 eggs from this stool, whereas the Willis method produced 56. It was surprising to find that in some light cases the total number of eggs recoverable was less than 5, and in some cases only 1. From case 16, for instance, we could obtain only 1 egg from a gram of stool on two different occasions, and on another occasion it was entirely negative. These stools were uniformly negative by all the other methods. Lane comes to the conclusion that 28 to 30 eggs per gram is the usual number which can be expected from a single normally ovipositing female hookworm, and this agrees with the findings of ourselves and others, but it is evident that the females do not always oviposit at the normal rate.

Assuming that the number of eggs recovered by the D.C.F. method from a gram of faeces by repeated centrifugal spins and examination of the pour-off (see *Trans. Roy. Soc. Trop. Med. & Hyg.*, 1924, Vol. 7, pp. 415-416), represents very nearly the total number of eggs present,—a conclusion which seems to be justifiable in the light of checks and controls made by Lane,—a comparison of this total with the estimate obtained by our modification of Stoll's egg-counting technique is of great interest. This technique was described in full elsewhere (Chandler, 1925); in brief it is as follows:—three grams of stool are thoroughly comminuted in 90 c.c. of N/10 sodium hydroxide in a small flask and two 0.3 c.c. samples are examined on uncovered slides; the average of the two egg-counts multiplied by 100 gives the estimated number of eggs per gram. Stoll's original technique consists in mixing 3 grams of stool with 45 c.c. of N/10 sodium hydroxide and the counting of eggs in a 0.15 c.c. sample of this on a covered slide. The opportunities for loss of eggs by camouflage are much greater in this than in our method. Lane got surprisingly uneven results from his modification of Stoll's method which he used as a control for his D.C.F. counts. Maplestone (1924) also reports unfavourably on this method, showing that there is

much camouflage of eggs. By using twice the quantity and double the dilution used by Stoll and examining for eggs on an uncovered slide on which the debris can be gently blown aside to expose eggs lying underneath, we felt confident that no appreciable number of eggs was being lost by camouflage. We averaged two counts from separately prepared suspensions from

different parts of a stirred stool in order to avoid errors due to sampling, but where the degree of infection in groups is being investigated these errors balance themselves and reasonably accurate estimates can be obtained from single counts on each stool sample.

The comparison with the D.C.F. totals shows that in almost every instance the egg-counts

* =Due to large number of eggs involved; only $\frac{1}{2}$ gram of stool was used for the suspension. The number for 1 gram based on the counts for $\frac{1}{2}$ gram are given underneath.

** =Due to very large number of eggs involved; the eggs recovered on first two or three spins were washed into a measured quantity of water, thoroughly stirred, and the number estimated from the average count of two samples. The number obtained on subsequent spins was added to this.

check with astonishing accuracy, in most of the low counts falling within the nearest 50 and in the higher counts the nearest 100. The only striking discrepancy in the whole series is in stool No. 5, in which the dilution counts indicated 950 eggs per gram and only 357 were obtained by the D.C.F. method. In this case, however, much debris floated up in the salt solution and probably interfered with the recovery of the eggs. The average number of eggs per person for the entire group, based on the totals obtained by the D. C. F. method, comes to 1,112, whereas based on the egg-count estimates it comes to 1,132, which is far closer than one might reasonably have expected from an egg-counting technique in which the eggs in only 1/100th of a gram are counted.

The substitution of the D.C.F. method for the Stoll egg-counting method for estimating egg output seems to us quite impracticable. Even assuming that with every detail of the technique carefully controlled 90 per cent. or more of the total eggs can be obtained on a single spin, when this number exceeds one or two hundred, which is more frequently the case than otherwise, the counting of the eggs is very burdensome; and when the eggs exceed five or six hundred an accurate count becomes quite impossible without spreading the drop over a large area or washing the eggs into a measured quantity of fluid and counting the number in a measured fraction, either of which involves time and labour. The results from our egg-counting technique indicate that it is fully as accurate as the D.C.F. method—even when the latter is pushed to finality—and it is certainly less troublesome, in that a single process is suitable for all degrees of infection. Where less than 100 eggs per gram are present only one or no eggs can be expected on two slides. If there is one egg on two slides an average of 50 is indicated, whereas two negative slides from a stool which has been shown to be positive by a concentrative technique can arbitrarily be regarded as having 25 eggs per gram without involving any great inaccuracy in a group estimate.

THE TOXICITY OF CARBON TETRACHLORIDE TO CATS. A WARNING

By ASA C. CHANDLER, M.S., Ph.D.,

In charge Hookworm Research Laboratory, Calcutta School of Tropical Medicine,

and

R. N. CHOPRA, M.A., M.D. (Cantab.),

MAJOR, I.M.S.,

Professor of Pharmacology.

ON account of conditions which made it difficult to keep dogs under observation for experimental work we attempted to use cats for a number of experiments on the toxicity of carbon tetrachloride under various conditions of diet, etc. In all we have given carbon tetrachloride to 87 cats, in various dosages and under various dietary conditions and have found the susceptibility of cats to this drug so great that it was impossible to get more than suggestive results from our various experiments. Ninety-two per cent. of the cats died or were killed in a dying condition, regardless of dosage or diet.

Hall and Shillinger (1923) state that carbon tetrachloride at the rate of 0.3 c.c. per kilo. is well tolerated by cats, and report ten experiments on five kittens, with doses of carbon tetrachloride ranging from 2 c.c. to over 11 c.c. per kilo., of which only two, receiving over 9 c.c. per kilo. each, died. Two of the kittens were treated three times, some of the doses being as high as 7 and 8 c.c. per kilo. These authors also report a statement by Dr. O. V. Brumley of the Ohio State University that "it (carbon tetrachloride) has been a great help, particularly in the treatment of hookworms in dogs and cats," and they record Dr. Buckingham of Washington as reporting favourably on the use of carbon tetrachloride, in cats. Hall and Shillinger conclude that, in so far as conclusions can safely be drawn from their experiments, carbon tetrachloride has a wide margin of safety for cats, between the therapeutic dosage of 0.3 c.c. per kilo. and the minimum lethal dose, and that members of the Felidæ as well as the Canidæ are highly tolerant to the drug.

Relying on these conclusions we selected 0.5 c.c. per kilo. as an experimental dosage, thinking that this would probably produce sufficient damage in unprotected animals so that an improvement could be noticed readily if we were successful in protecting the animals against the effects of the drug. The carbon tetrachloride we used is the same as that used in our hospital for human cases, is free from carbon bisulphide and phosgene, and conforms to the other usual standards of purity for carbon tetrachloride.

As a preliminary we administered 0.5 c.c. per kilo. to six full-grown cats (1,600 to 3,000 grams) by stomach tube about three hours after food. Of these six, three died on the

second day, two more on the third day, and the last one, which was dying, was killed on the same day. This result was so much at variance with what we had expected from Hall and Shillinger's results that we repeated the experiment using kittens weighing from 670 to 940 grams, similar to those used by Hall and Shillinger. Of these six, two died on the second day, two died on the third day, one which was in a dying condition was killed on the same day, and the sixth one died on the fourth day. In another batch of full-grown cats, one died on the day following treatment, and all the other five died on the second day. It is needless to go into detail here regarding the attempts at protection against the effect of carbon tetrachloride which we tried, since these will be fully discussed in another paper. Suffice it to say that nothing we tried in the way of diet, purging, or other preparation succeeded in saving more than two out of six cats, and this only in one instance; the best we could do in most cases was to delay death to the third and fourth days instead of the second and third days. In four cases death occurred on the fifth day, and in three instances the cats did not die until the sixth, eighth, and eleventh days respectively. Of 49 cats which were given 0.5 c.c. per kilo., only 4 survived; of 27 which were given 0.25 c.c. per kilo., 3 survived; and of 12 given 4 c.c. per kilo., all died. We had no difficulty with vomiting in the case of the smaller doses, but ten of the twelve which were given 4 c.c. vomited within about half an hour. Altogether, 8 cats out of the 87 died on the day following treatment, 30 on the second day, 23 on the third day, 7 on the fourth day, and 4 on the fifth day; 5 were killed when in a dying condition, and 7 survived. Four of the eight which died on the day following treatment had vomited, from which we deduce that very likely death was hastened by inhalation of carbon tetrachloride from the vomitus.

We cut sections of the liver and kidney of all these cats, and sections of the spleen, suprarenal, and intestinal wall of many of them. We found no significant changes in the spleen, and in only a few instances we found slight damage of the outer cortical cells of the suprarenals, which was quite in contrast with the necrosis reported by Phelps and Hu (1924). The intestinal wall in some instances showed the villi severely congested and occasionally denuded of the epithelium. The really important lesions were found in the liver and kidneys. The liver in every instance showed the central necrosis which is so characteristic of carbon tetrachloride, and usually a very extensive fatty degeneration was present. From 25 to practically 100 per cent. of the liver tissue was damaged even in cats which received only 0.25 c.c. per kilo. Most remarkable, however, were the lesions found in the

kidneys, and in many if not most instances we believe that the renal rather than the hepatic damage was the actual cause of death, and that the susceptibility of this organ in cats accounts for the much greater toxicity of carbon tetrachloride for cats than for dogs. The convoluted tubules show extensive fatty degeneration and frequently necrosis, but the collecting tubules are as a rule little affected; there is often desquamation—sometimes very extensive—of Henle's loops. The Bowman capsules are frequently infiltrated with blood, and the glomerular endothelium is swollen and the vessels dilated. In every instance in which we were able to obtain urine at autopsy there was albumen present, often in great quantity, and there was frequent evidence of blood.

We are quite at a loss to account for the striking differences between our results and those of Hall and Shillinger, but we are convinced that it is very unsafe to attempt the treatment of feline animals with carbon tetrachloride and therefore give warning against its use.

"DIAGNOSIS" IN HOSPITALS.

By C. C. MURISON, F.R.C.S.E., D.P.H., D.T.M.,

LIEUT.-COLONEL, I.M.S.,

Civil Surgeon, Belgaum.

BEFORE discussing the question of "diagnosis" in hospitals it will be advisable to make a few remarks about the grouping of patients, which appears in several places of this paper. With a view to the preparation of accurate statistics it has been found that all the patients of some hospitals, owing to local conditions, cannot be counted together. Therefore to overcome this difficulty different groups have had to be formed so that each patient either on admission into hospital or as soon as possible after admission, that is on the case being diagnosed, must be placed in one of these groups; and the patients of each group will be enumerated in that group and not with the patients in the other groups.

The groups vary according to local conditions but some of them are:—

1. Ordinary:—Most of the patients are in this group.
2. Transfer:—Patients received as transfers from other hospitals and to prevent them from being enumerated more than once.
3. No appreciable disease:—Patients with no disease and to prevent them from being enumerated with those with a disease.

4. Pregnancy:—These patients are admitted to await their confinement and during this period are shown in this group.

5. Etc., etc., etc., etc., etc., etc.

For brevity, diseases and injuries, except in a few instances, will be mentioned as diseases.

It is absolutely essential that all diseases must be diagnosed according to some definite method, otherwise it is quite impossible for statistics to be compiled with any accuracy.

The authorities of the majority, if not all hospitals and dispensaries, diagnose the diseases of their patients in accordance with "The Nomenclature of Diseases," published by the College of Physicians, London. The authorities of the military hospitals in India diagnose the diseases of their patients not only in accordance with "The Nomenclature of Diseases," but also certain diseases of their patients in accordance with special lists published, from time to time, in "Army Instructions, India," and not in accordance with "The Nomenclature of Diseases."

It is hoped that when another edition of "The Nomenclature of Diseases" is to be published the special lists of diseases published by the military medical authorities will be considered with a view to being embodied in it.

It is a pity that the serial number of the diseases in "The Nomenclature of Diseases" has been done away with in the 1918 edition, as these numbers used to facilitate greatly the work of finding and of checking the various diseases. The usefulness of these numbers was by many not realised till they began to diagnose the diseases with the 1918 edition of "The Nomenclature of Diseases"—that is, when the serial number of the diseases had been done away with. These numbers, if they had not been done away with, would have been very useful, if used only (and not the name of the disease) for showing the patient's disease on his or her case card, which is hung in the ward, and also in the register of the patients, till the auditors had finished auditing the books, when the name of the disease could be entered.

The reader's attention is drawn to the following in the 1918 edition of "The Nomenclature of Diseases":—

(a) Memorandum by sub-committee on classification on p. 10.

(b) The footnotes on the pages.

(c) The diseases themselves. The author recommends that no diseases should be diagnosed till the instructions about that disease in "The Nomenclature of Diseases" have been considered.

As an example let us consider the diagnosis of "small-pox." Besides diagnosing the case as "small-pox" we have to state additional information as seen from the following extract from "The Nomenclature of Diseases" regarding "small-pox":—

"Small-pox. Synonym, variola."

In every case the presence or absence of marks of vaccination, and when marks are present, their

number, size and character should be noted. Any reliable information should be added as to whether the patient was unvaccinated; vaccinated in infancy only; vaccinated after infancy (state age if known); vaccinated only after infection with small-pox; or revaccinated (give dates if known).

If possible the diagnosis should be made in accordance with the cause of the disease and the pathological or local condition should also be specified. In the case of one or more organs or localities being principally affected it should be stated.

The pathological or local condition should be diagnosed only when all available means have failed to find the cause of the disease. The following few examples will explain the above statement:—

(a) Tubercle of the lungs should be diagnosed as "tubercle, lungs, etc." and not as "phthisis." The latter condition, as stated above, used to be diagnosed only when all means had failed to detect the tubercle bacillus. "Phthisis" no longer appears in "The Nomenclature of Diseases."

(b) Abortion. Cases of "abortion," say due to "syphilis" in most hospitals are diagnosed as "abortion" and not as "syphilis" and yet in the case-sheets or cards a remark about the patient suffering from "syphilis" will be found. The abortion in these cases is really a sign or symptom just as much as vomiting and purging are in the case of cholera. The latter are diagnosed not as vomiting and purging but as "cholera" and so the former should be diagnosed not as "abortion" but as "syphilis." Under the present rules and registers of patients a remark about the abortion should be made in the "remarks" column.

(c) Cases of enlarged spleen due to, say, malaria or kala-azar are diagnosed, not as "enlarged spleen," but as "malarial cachexia" or "kala-azar" as the case may be. "Enlarged spleen" is diagnosed as such only after failure to trace the cause of it.

(d) Pyrexia of uncertain origin (P.U.O.) should not be diagnosed as such till all the most recent available methods of examination have failed to reveal the cause of the pyrexia from which the patient is suffering.

Injuries.—In all cases of injuries state:—

1. Whether (a) self inflicted; (b) judicial; (c) homicidal; or (d) received in battle.

2. Mechanism or agent causing injury.

3. (a) Chief injury caused in 1 (a), 1 (b) and 1 (c). The additional injuries, if any, to be entered in the "remarks" column.

(b) The injuries caused in 1 (d). All wounds and injuries received in action should be diagnosed in accordance with the instructions on the fly-leaf of the admission and discharge book (A.B. 27a). The remarks made below under two or more diseases or diseases and injuries do not preclude a full entry being made of all wounds and injuries received in action.

Example:—

- (1) I (4) G.S.W. Head; penetrating cranium.
- (2) IV (2) G.S.W. Chest; fractures 4th rib, right.
(G.S.W. = Gunshot wound).

Wound.—Incised Umbilical Cord.—There is no uniformity in maternity hospitals about showing newborn infants as patients of the hospital. One of the following procedures is usually adopted:—

(a) They are not shown as patients till they develop some illness from which they are likely to die.

(b) Those developing an illness are shown and those not developing an illness are not shown as patients.

(c) All are shown as patients either for some illness from which they are suffering or for "umbilical dressing."

This shows that the statistics of these hospitals are incomparable.

This defect should be remedied and so the author suggests that all newborn infants in a hospital should be shown as patients of that hospital by admitting them either for an illness from which they are suffering or for some condition which should be decided by a central committee.

All newborn infants require dressings for the umbilical cord but this is not shown as a disease in "The Nomenclature of Diseases" and so these cases of healthy newborn infants cannot correctly be returned as "umbilical dressing."

The author is of the opinion that pending the decision of the central committee these cases should be admitted for "wound—incised umbilical cord." This condition is in keeping with the requirements of "The Nomenclature of Diseases."

It may be argued that the admitting of healthy newborn infants as patients of a hospital is merely to swell the numbers of the patients with the object of showing a larger number of occupied beds for financial purposes. This argument is absurd as all newborn infants whether they are suffering from a disease or not have to be supplied with a crib, bedding, clothing, medicine, dressings, perhaps diet and also have to be bathed and looked after and so they entail expenditure under several budget heads, which can legitimately only be met by showing them as patients. If they are not shown as patients then how is this expenditure on their account to be met?

Debility.—This is a very common diagnosis and formerly orders were issued to the effect that this term should only be used when the cause of the condition was not traceable. It is not mentioned in the 1918 edition of "The Nomenclature of Diseases" and so it is imperative that all persons suffering from so-called "debility" must be diagnosed under its cause. In the past a common method of getting over this difficulty was to diagnose these cases as "anæmia" and this no doubt will be the procedure adopted in the future. So statisticians look out for this!

It is regretted that a large number of the diseases in "The Nomenclature of Diseases" are not diagnosed in accordance with the rule that diseases should be diagnosed under their "causes" and the local or pathological condition produced should also be specified. Let us take the following example with the object of explaining this statement:—

Syphilis in the primary and secondary stages is diagnosed as such, and in the tertiary stage it is diagnosed, not as "syphilis," but in accordance with the pathological condition produced, such as, say, "locomotor ataxia." This latter diagnosis is quite legitimate when the cause of the pathological condition is neither known nor found in the patient, but it is unscientific to diagnose a case in accordance with the pathological condition produced and not in keeping with the cause of the condition. During the last few years venereal diseases have come to the front a great deal, and we frequently read all kinds of statistical figures in support of adopting some measure. The question arises "Can any reliance be placed on these statistical figures when a large percentage of the syphilitic cases in the tertiary stage, as stated above, are diagnosed, not as syphilis, but as the pathological condition produced?"

The author is of the opinion that a very large number of these syphilitic cases are not included in the statistical figures of syphilis.

This raises the question of the terminology of the cause of many well-known diseases. The diagnosis of "syphilis" for the primary and secondary stages is of old standing, but the author is of the opinion that we should be in keeping with modern knowledge and diagnose it, in all the three stages, as regards the cause, not as "syphilis," but as "*Spirochæta pallida* disease."

This principle should be adopted all through the science of diagnosis.

As regards the pathological changes produced in the tissues by the disease sufficient attention is not paid from a statistical point of view, although the diagnosis of these changes is noted very fully in the case papers of the patient concerned. The author suggests that these changes should be noted fully in the diagnosis of the cases and entered in the register of patients. To explain this statement let us take the case of "gonorrhœa" in the male. From a statistical point of view it is quite sufficient to enter this case in the register of the patients as "gonorrhœa," and in a few exceptional cases, such as the eye, nothing is mentioned about the tissues affected or the extent to which they are affected. The latter from a treatment and prognosis point of view is very important, and so it is diagnosed in the case papers of the patient, but no record is kept in the register of patients. Consequently this information is not included in the statistics of the hospital. Suppose a big percentage of the gonorrhœa cases are discharged from the hospital as "otherwise relieved" or

"incurable" and so the natural question which will be raised is "Why is this the case?" The answer will be found, not in the register of patients, but in the case papers of the patients, and to look up these papers will entail many days or even weeks of hard work. If the diagnosis of the tissues involved and the extent to which they were involved were entered in the register of patients it would facilitate greatly the answer to many of the questions which arise, and further make the statistics of the hospital more interesting. Now in the case of gonorrhoea in the male, besides diagnosing "gonorrhoea," we should state whether the condition is acute or chronic, the tissues involved, and the extent to which involved, such as anterior urethra, posterior urethra, or both; surface or deeper tissue affection; and complications such as vesiculitis, epididymitis, orchitis, prostatitis, rheumatism, etc.

Again the term "gonorrhoeal rheumatism" is used in a very vague sense. The question is "What does rheumatism mean?" The answer, on looking up books, is that it is an affection of joints, heart and its membranes, or both. Some books include "chorea" under rheumatism. In "The Nomenclature of Diseases" rheumatism is diagnosed under "rheumatic fever."

From the above it will be seen readily that there are many difficulties in diagnosing diseases, but it is hoped that with our advancing knowledge of the causes of, and of the pathological changes produced in the tissues by diseases it will not be long before we are in a position to decide on some sound scientific principles for the diagnosing of all diseases.

In the meantime the author is of the opinion that all diseases should be diagnosed, as far as practicable, in accordance with the cause of the disease as well as with the pathological condition produced. This, if approved, will necessitate the "diagnosis" column in the register of patients to be sub-divided into the following two sub-columns:—

(1) *Cause of disease.*—In many diseases we know the pathological condition produced, but we are unable to state the cause of it, and so this sub-column in these cases must be shown as "?".

(2) *Pathological condition produced.*—In several conditions we may know the cause of the disease, but owing to our limited knowledge, we are unable to state the pathological condition produced, and so it is essential to state the important sign or symptom present, such as jaundice, melancholia, mania, etc.

The question of the diagnosis of disease, owing to the present system, must be considered from a scientific as well as from a statistical point of view.

Many medical officers diagnose the diseases scientifically, and where necessary fit them into those mentioned in "The Nomenclature of Diseases"; while others diagnose the diseases according to "The Nomenclature of Diseases"

and quite ignore the scientific diagnosis. Hence, till "The Nomenclature of Diseases" meets these requirements, it is suggested that the "diagnosis" or "disease" column of the register of patients should be divided into "statistical" and "scientific" columns. The necessity for this can be more fully explained by taking the following examples:—

Cases of "typhoid," "paratyphoid A" and "paratyphoid B," although scientifically separate diseases, were shown as "enteric" in the 1906 edition of "The Nomenclature of Diseases." That is, statistically they were considered one disease. The 1918 edition of "The Nomenclature of Diseases" shows them as:—

(a) Typhoid fever.

(b) Paratyphoid fever.

In the military department in India "enteric" has been substituted by:—

(a) Typhoid fever.

(b) Paratyphoid "A" fever.

(c) Paratyphoid "B" fever.

The diagnosis of these three is based on the isolation of the specific organism.

(d) Enteric fever is diagnosed clinically or on a rising Gruber-Widal reaction and the organism is not isolated.

New Infections and Relapses.—Infective diseases like malaria and venereal diseases in the military medical department in India are further diagnosed as to whether they are "new infectious" or "relapses" as seen in the following:—

Malaria. (a) Quartan: new infection.

" : relapse

(b) Benign tertian: new infection.

" : relapse.

(c) Malignant tertian: new infection.

" : relapse.

(d) Malarial cachexia.

(e) Clinical: new infection.

" : relapse.

Syphilis. (a) Acquired: new infection.

" : relapse.

(b) Congenital.

Soft chancre: New infection.

Relapse.

Gonorrhoea: New infection.

Relapse.

Two or More Diseases.—Frequently patients suffer from two or more diseases, and it is quite absurd to show the one patient as two or more patients in accordance with the number of the diseases from which he or she is suffering. According to the rule the most important of the diseases from which a patient is suffering is diagnosed and entered in the "diagnosis" column of the register of patients. This, of course, does not mean that the other diseases from which a patient is suffering are not to be mentioned in the case-sheet or card, and the author further suggests that, although it has never been done as far as

he knows, the additional diseases should be entered in a special column of the admission and discharge card and of the register of patients, and additional disease cards for each of these additional diseases be made and kept separate from the cards of the diagnosed diseases. It is quite possible that later one of these additional diseases becomes more important than the diagnosed disease, of which the patient may be better or cured, and in this case the patient can be discharged from the entry in the register of patients by "new disease having supervened," and re-admitted in another entry in the register of patients by "new disease (one of the additional diseases) having supervened."

At present it is impossible to conjecture how valuable this recording of the additional diseases may be in the future, near or remote. It may be found that in some cases these additional diseases, along with the diagnosed disease, are perhaps only the signs or symptoms of some particular disease. It is very difficult to state whether signs and symptoms should also be entered in this column of additional diseases, and further, "What is a sign or symptom and what is a disease?" In this connection it is advisable to take an example, such as a patient suffering from "intestinal stasis and melancholia." The author has both heard and read good arguments in favour of the melancholia being secondary to the intestinal stasis, and also in favour of the intestinal stasis being secondary to the melancholia. The author is of the opinion that melancholia is nothing more than a symptom, and if the intestinal stasis is secondary to the melancholia, then the pathological condition, whether in the brain or elsewhere, or the cause of the pathological condition should be diagnosed. Our knowledge in these matters at present is very limited and hence the great difficulty. The day will arrive when these conditions will be diagnosed more definitely. Till then we must content ourselves by diagnosing some cases by the chief sign or symptom present. The medical attendant must use his or her discretion in diagnosing the case, and also in entering the additional important diseases, signs and symptoms in another column (additional diseases column) of the register of patients, as well as in the admission and discharge card, additional disease card, and in case papers or cards.

Women patients come to the ante-natal department of a hospital either to find out whether or not they are pregnant, or for advice about some condition which is either the result of the pregnancy, or of some disease which they have in addition to being pregnant. These cases will come under one of the following categories:—

(a) *Not pregnant and healthy women.*

These women are neither pregnant nor diseased, and so should be granted register numbers in the "no appreciable disease" group to prevent their

being enumerated amongst the patients who are suffering from a disease.

(b) *Not pregnant but suffering from some disease.*

These patients are suffering from a disease, and so should be diagnosed as such and granted a register number in the appropriate group.

(c) *Normal pregnancy in a healthy woman.*

Being a normal pregnancy, which is a physiological and not a pathological condition, there is no place in the usual returns of either a general or a special (ante-natal) hospital to show such cases. Consequently to get over this difficulty it is quite a common practice to diagnose these cases, not as "pregnancy," but as some slight sign or symptom of pregnancy, such as "vomiting" or "constipation," which the patient states she has. This is quite wrong, as it causes incorrect statistics. The remedy for this is to amend the return forms so as to show the cases of "pregnancy," but till this is done these cases of "pregnancy" should be shown in the returns against or under "no appreciable disease," and a remark made in the space for remarks to the effect that so many of these "no appreciable disease" cases are of "pregnancy." These cases in the register will be diagnosed as "pregnancy," and granted register numbers in the "pregnancy" group.

(d) *Aggravated form of one of the signs or symptoms of pregnancy, such as "vomiting," which requires treatment.*

These cases invariably are diagnosed as "vomiting," as they are under treatment for it and not for pregnancy. The author is of the opinion that this procedure is quite wrong. Just as vomiting is a symptom of "*Ascaris lumbricoides*" so vomiting—mild or severe—is a symptom of "pregnancy." The former is diagnosed as "*Ascaris lumbricoides*," and not as "vomiting," and so the latter should be diagnosed as "pregnancy" and not as "vomiting." These cases of pregnancy, as suggested in the pregnancy group of the register of patients, should be granted register numbers in the "pregnancy" group. Till the forms for submitting returns are amended, these "pregnancy" cases, as suggested in (c) above, should be shown against or under "no appreciable disease," and a remark made in the space for remark to the effect that so many of the "no appreciable disease" cases are of pregnancy, and so many of these pregnancy cases have vomiting.

(e) *Some disease, such as "nephritis," which is either due to or aggravated by pregnancy.*

These cases are either suffering from a disease or have a tendency towards that disease, and the pregnancy is only the exciting cause, and therefore these cases are correctly diagnosed as suffering from "disease." In the "remarks" column of

the present register of patients, or in the "additional diseases" column of the register suggested by the author, "pregnancy" should be entered.

Many held the view that albuminuria in pregnancy is due to pregnancy, and if the pregnancy was not there the patient would not have albuminuria or go on to eclampsia. If this view is correct, then pregnancy is a disease, and should be shown as such. These are debatable points and should be decided by experts on the subject.

(f) *Some disease, such as "syphilis," which exists along with the pregnancy.*

These cases are really under treatment for the disease (syphilis) and so should be shown as "syphilis" and granted a register number in the "venereal" group.

Now that ante-natal work has come to the front so much, it is hoped that experts will decide on a form for the submission of returns which will include all the above categories, but pending that, the author suggests that all return forms should have separate tables to account for respectively the following categories:—

- (1) Cases of "no appreciable disease."
- (2) Cases of disease (and not pregnant).
- (3) Cases of normal pregnancy.
- (4) Cases of pregnancy with one or more aggravated signs or symptoms of pregnancy.
- (5) Cases of disease aggravated by pregnancy.
- (6) Cases of disease co-existing with pregnancy.

Disease Supervened.

"Disease supervened" is a term used when a patient is discharged on paper—that is, from the entry in the register of patients for the disease from which he or she has been diagnosed as suffering,—and is re-admitted in another entry in the register of patients for the disease from which he or she is also suffering or has just developed, and which is more important than the previously diagnosed disease, and so it must necessarily be shown against the patient. The following examples will explain this:—

Frequently a patient recovers or greatly improves from the diagnosed disease, or one of the additional diseases from which he is suffering becomes worse to such an extent that it becomes more important than the diagnosed disease. In these cases the patient is discharged, on paper—that is, from the entry in the register for the disease for which he or she was originally admitted (diagnosed disease)—and re-admitted under another entry in the register as a new case for the disease which has become more important, and granted a fresh register number in the appropriate group; and in the "remarks" columns of the two entries the following remarks are respectively made:—"Discharged by new disease having

supervened, vide No. . . . and "admitted by new disease having supervened, vide No. . . ."

Again a patient is admitted into hospital for some particular disease and later he or she develops a second disease which is more important than the original disease and necessitates a fresh entry in the register. In this case the same procedure as that described above is adopted.

Confinement Supervened.

"Confinement supervened" is a term used in a similar way to "disease supervened."

Pregnant women are admitted into hospital for the conditions noted below, and are shown in the "diagnosis" column of the register of patients as noted against each:—

Condition.	"Diagnosis" column.
(a) Confinement	Pregnancy.
(b) Aggravated sign or symptom of pregnancy, such as "vomiting"	Pregnancy.
(c) Some disease which is either due to or aggravated by pregnancy, such as "nephritis"	Nephritis.
(d) Some disease which is quite independent of the pregnancy, such as "syphilis"	Syphilis.

While these patients are in hospital labour pains begin, and so they are transferred to confinement wards. As confinement is a physiological, and not a pathological condition, these patients are dealt with in a manner similar to that in the case of "disease supervened"—that is, they are discharged from the entry in the register of patients for one of the above noted conditions for which they have been admitted, and re-admitted in another entry in the register of patients for "confinement," and granted a register number in the "confinement" group. In the "remarks" column of these two entries in the register of patients the following respective remarks should be made:—

"Discharged by confinement having supervened, vide No. . . ."

"Admitted by confinement having supervened, vide No. . . ."

In the event of the confinement case becoming abnormal, then treat her, as suggested above for "disease supervened,"—that is, discharge her from the entry in the register of patients for confinement by "new disease having supervened,"—and re-admit her in another entry in the register of patients for the abnormal confinement condition by "new disease having supervened," and grant her a register number in the "ordinary" group.

On the patient recovering from either the normal or the abnormal confinement (latter condition amounts to a disease) discharge her in the usual way.

In the event of the patient recovering from either the normal or the abnormal confinement,

but still suffering from either of the conditions mentioned above in (c) or (d), then deal with her as recommended for "disease supervened." that is, discharge her from the entry in the register of patients for the normal or the abnormal condition by "new disease having supervened," and re-admit her in another entry in the register of patients for the condition of (c) or (d) by "new disease having supervened."

In all the above transactions of "new disease and confinement having supervened" the appropriate columns of "condition on discharge" should be completed in accordance with the condition of the patient.

Disease or Confinement Supervened in a Case in one of the Transfer Groups.

In the event of a new disease or confinement having supervened in a case with a register number in one of the "transfer" groups, the register number for the re-admission—that is, for the new disease or confinement, must be in one of the appropriate groups for a direct admission and not in a transfer group. This case, as regards the re-admission, must be enumerated in the statistics of the hospital in which the disease or confinement supervened, while the admission in the "transfer" group, as explained under "transfer group," must be enumerated, not in the statistics of this hospital, but in those of the hospital which originally admitted the case, or in those of the original transferring hospital in the event of the case having been transferred from hospital to hospital more than once.

Results of Disease or Injury.

The results of a disease or injury should not be confused with a new disease supervening in a patient. For instance, a patient has been admitted for, say, fracture of the right humerus, and two or three weeks later he develops "wrist-drop." This "wrist-drop" is not a new disease but is the result of the fracture and therefore the patient must not be discharged and re-admitted on account of a so-called new disease "wrist-drop" or "musculo-spiral nerve paralysis" supervening but the patient must be continued to be shown for the fracture of the right humerus. (In passing, it may be stated that the particulars about fractures which have to be recorded will be found on p. 160 of the 1918 edition of "The Nomenclature of Diseases").

Disease Changed. (Error in Diagnosis).

"Disease changed" is a term used when a wrong diagnosis has been corrected.

It is advisable not to erase completely the wrong diagnosis, but to run a thin black line through it, so that it may be legible always. The idea of this is that if any reference is made in the future to account for the two diagnoses, this procedure will show at a glance that the erased diagnosis is wrong, and the diagnosis entered in

black above or below it is the correct one. If one or more returns have been submitted it is suggested that a red line be run through the wrong diagnosis, and the correct diagnosis entered in red ink, either above or below it, and further, that there be sent to the authorities concerned correction slips regarding the returns affected. A copy of the correction slips should be kept along with the corrected office copy of the return or returns thus affected. The erasure of the wrong diagnosis being with a red line and the entry of the correct diagnosis in red is to show that returns have been submitted with wrong diagnosis.

It may here be stated that on several occasions argument have occurred as to whether a diagnosis is to be changed or supervened. The author in these arguments has always taken the example of a case of chronic bronchitis, which later is found to be one of tuberculosis. The question arises as to whether the case was really a case of tuberculosis from the beginning or whether tuberculosis supervened on the bronchitis. If the former, the case is met by "disease changed," and if the latter, by "disease supervened." This cannot be decided by the registrar or his clerks, but must be decided by the physician in charge of the case, who is really the best judge. The diagnoses of all diseases are done by the physician or surgeon in charge of the respective cases, and so should this be.

Disease Changed in a Case in one of the Transfer Groups.

In the event of the disease of a case with a register number in one of the "transfer" groups being changed intimation to this effect should be sent to the hospital whence the case was received as a transfer, so that the records of that hospital can be corrected accordingly. The authorities of the latter hospital, if they have received the case from another hospital, should pass on the same intimation to that hospital for the same purpose. This intimation should be passed on in this way from hospital to hospital till it is received in the hospital where the patient in question was originally admitted—that is, where the patient was granted a register number, not in a "transfer" group, but in one of the appropriate groups usually granted to the original or direct admissions.

Observation for Some Infectious Disease.

It is quite a common practice for medical practitioners and others to report to the medical officer of health all suspicious cases of infectious diseases. These suspicious cases are, under the orders of the medical officer of health, admitted into an isolation hospital for observation for that particular infectious disease. For the convenience of explanation let us take as an example—"observation diphtheria."

The admission of this case into an isolation hospital is reported in the "daily state" by the medical superintendent of the isolation hospital to the medical officer of health.

One of the following two procedures is carried out in these observation cases:—

(1) If after some days this case is diagnosed as "diphtheria," then the patient is discharged from the entry in the register of patients for "observation diphtheria," and re-admitted in another entry in the register of patients for "diphtheria," as if he or she were a new patient, and the medical officer of health is informed of this paper transaction through the medium of the "daily state" of the isolation hospital, submitted by the medical superintendent.

(2) In the event of this case being diagnosed neither as "diphtheria" nor as any other infectious disease, then the entry in the records is continued as "observation diphtheria" as if it were a disease, and it is shown in all returns as "observation diphtheria."

It is said that the above methods have been adopted with a view to making the figures in the isolation hospital tally with those in the office of the medical officer of health.

The author is not only quite unable to see the reason for adopting the above methods, but is also of the opinion that they are faulty and unscientific.

The medical officer of health gets a "daily state" from the isolation hospital, and so his figures must tally with those of the isolation hospital.

The procedure under (1) above means that the one patient has been admitted into hospital for two diagnoses, and consequently becomes two patients, and also that the number of days in hospital for "observation diphtheria" is excluded from the number of days in hospital for "diphtheria," while really the patient during both the periods in hospital has been there for the one disease—"diphtheria."

In the returns the one patient is shown as two patients suffering respectively from "observation diphtheria" and "diphtheria." These above mentioned transactions have entailed additional clerical work.

The procedure under (2) above is quite wrong, as there is no such disease as "observation diphtheria." It is presumed that all these patients are suffering from some form of sore-throat and should be diagnosed as such.

It has been argued that medical officers of health and medical superintendents of isolation hospitals are prejudiced against showing non-infectious diseases in their records and returns, and so they show these cases as "observation for some infectious disease." This is taking a wrong view of the actual facts. In all isolation hospitals, during the course of a year quite a large number of the cases sent in by practitioners, diagnosed as suffering from some infectious disease, prove to be some non-infectious disease, and so these cases should be finally diagnosed, not as "observation for some infectious disease," but in accordance with "The Nomenclature of Diseases." These

cases, even if transferred to some general hospital for further treatment, must be accounted for during the days spent in the isolation hospital, and, from a statistical point of view, their exact disease should be diagnosed, as stated above, in accordance with "The Nomenclature of Diseases."

The author remembers a patient with a severe sore-throat in whose throat swabs no diphtheria bacilli were found, and so the case was diagnosed as "acute ulcerative tonsillitis." About two weeks after discharge from hospital the patient complained of food, especially fluids, regurgitating through the nostrils. This symptom was sufficient to diagnose the case as "diphtheria," and so the disease of this case was changed to "diphtheria," and the medical health authorities were informed of this change of diagnosis.

There are many diseases which take several days, if not weeks, to diagnose, and so the rule should be that only a pencil entry under "diagnosis" in the records regarding the most important sign or symptom (vide N.Y.D.) should be made, and when the diagnosis has definitely been made it should be entered in the records after erasure of the pencil entries.

No Appreciable Disease. (N.A.D.)

The diagnosis of the patients who on discharge from hospital are found not to be suffering from any disease is usually shown as "N.A.D.," which stands for "no appreciable disease."

Not Yet Diagnosed. (N.Y.D.)

With a view to enable the returns of the hospital to be submitted at the appointed time, it is found convenient to show all cases which have not been diagnosed as "N.Y.D.," which stands for "not yet diagnosed," and in the "remarks" column of the returns further notes should be made about each case, and in these notes the main signs or symptoms should be brought out, such as jaundice, fever, cough and fever, paralysis of one leg, etc., or it should be stated that the case is under observation for some particular disease. These cases, when diagnosed, should be shown either in the succeeding returns of the hospitals or in correction slips.

Diagnosis made in a "N.Y.D." Case in one of the Transfer Groups.

When a diagnosis is made in a "N.Y.D." case with a register number in one of the "transfer" groups, the procedure regarding the sending of an intimation as given under "disease changed in a case in one of the transfer groups" should be adopted.

Veneral Sore.

In many hospitals all the suspicious "venereal sores" instead of being shown temporarily as "N.Y.D.," as stated under "N.Y.D." above, are temporarily diagnosed in pencil as "V.S." (venereal sore) or as "N.Y.D., V.S." (not yet diagnosed, venereal sore). On one of these cases

being diagnosed definitely as "syphilis" or "soft chancre," the above temporary diagnosis in pencil is erased with india-rubber and in its stead the correct diagnosis is entered. In the returns appropriate remarks, as suggested under the system of "N.Y.D.," will have to be made. The author does not see the necessity for this procedure in preference to that of the "N.Y.D.," but he is merely bringing it to the notice of the reader as it is the custom of some hospitals.

Diagnosis made in a Venereal Sore or Not Yet Diagnosed Venereal Sore in one of the Transfer Groups.

When a diagnosis is made in a "venereal sore" (V.S.) or "not yet diagnosed venereal sore" (N.Y.D., V.S.) case with a register number in one of the "transfer" groups, the procedure as given under "disease changed in a case in one of the transfer groups" about sending an intimation should be adopted.

OBSERVATIONS ON CASES OF DEMENTIA PRÆCOX.

By FRANK NORONHA, M.B., C.M., D.P.M. (England),
Superintendent, the Asylum, Bangalore.

SINCE Kraepelin recognised it as a distinct disease nearly thirty years ago, dementia præcox has been an interesting field for research and speculation among psychiatrists. Several controversial matters regarding it, e.g., whether it is a clinical entity or not, or whether it is physiogenic or psychogenic, are still unsettled. But controversy apart, on a close observation of cases, one finds several points of similarity to the symptoms described by Kraepelin and grouped together by him under the designation of dementia præcox.

A recognition of the early symptoms of this disease is of importance to the general practitioner, for though the term "dementia" applied to this disease would connote incurability yet there is a prospect of rehabilitating the patient and preventing permanent mental breakdown if the case is taken in hand early. Dementia præcox was not returned as a separate disease in the annual reports of mental hospitals until very recently, such cases being shown as mania or melancholia or "dementia of other forms" according to the prominent symptom observed in each case. The annual report of the Ranchi European Mental Hospital for 1921 shows 11 out of 49 admissions or 22.4 per cent. as cases of dementia præcox. In the Punjab hospital in 1921, 29 out of 345 or 8 per cent. were returned under this head. In the report of the mental hospitals in Bengal for the years 1921-23, out of a total of 213 admissions, 41 or 19 per cent. were for dementia præcox. In the annual reports of the Asylum, Bangalore (Mysore State) dementia præcox has not hitherto been shown in a separate column, but from the notes on cases it is found that nearly 30 per cent. of those admitted during 1923 were of the præcox type.

The disparity in the figures quoted above is explainable from the fact that there is great room for doubt as to what exactly constitutes dementia præcox. Professor Kraepelin himself admits that "the complexity of the conditions which we observe in the domain of dementia præcox is very great." But though in details these cases may differ, yet "dementia præcox on the whole represents a well characterised form of disease."

In the majority of cases there is a history of the patient having run away from his home and in his travels having come in collision with the law and thereby being recognised as insane for the first time. This impulsive act so characteristic of the disease leads later on to other irregularities of conduct which land the afflicted person into trouble and finally into the asylum. After leaving their homes these patients take to wandering at large without any aim. Generally they drift from the village into the city. Some join a travelling wedding party or a group of pilgrims to a shrine. Others wend their way with crowds of country folk towards the capital city for the annual festival. A few have been known to resort to a hill or a jungle, being discovered later on in a semi-starved condition.

This phase of vagabondage is often preceded by a display of intense dislike to the people of the house. "Strikes parents, ill-treats wife and children" or in the case of females "neglects household work, breaks pots and pans" is given as the early symptom in these cases.

On admission into the hospital most of these patients appear at first sight to be so placid and apparently so coherent in their replies to questions (though reticence is the rule with them) that they seem to belie the history usually accompanying them of wandering at large or molesting passers-by. Their memory is correct for all important events in their life, but their emotional instability is easily noticed in the senseless laughter or purposeless smile which accompanies their answer even to a serious question. Of course the patient denies the charge made against him of wandering at large. If he is asked the reason for leaving his home, he gives an apparently rational answer such as search for a job, visiting a large city or going to a festival.

Within a few days—or sometimes within the first 24 hours—of admission into the asylum he shows evidence of the true nature of his malady. He has either snatched another patient's food or of a morning he is found to have torn his clothes into rags or smeared himself and the walls of his room with faeces or has carefully bundled the excrement in a part of his garment. The reason for this is not forthcoming. When a maniacal patient in his stress of activity tears his clothes he has a reason ready to account for his act. He would say that he wished to convert one garment into two or that he wanted to renew it. But a præcox patient has no such answer

ready but a bare denial, with a purposeless smile. The combination of bizarre conduct with a clear consciousness and good apprehension of surroundings and perhaps good memory can only be regarded as a dissociation of mental structure in such a way that the dissociated portions regress to earlier levels of mental life. This disordered conduct persists for a considerable time until as a result of watchfulness or other treatment the patient may revert to his normal conduct and adapt himself satisfactorily.

Another set of cases display a "negativistic" impulse which takes the form of "mutism." The history in these cases is that the patient gradually became seclusive, indifferent to his usual work, reticent in conversation and finally quite mute, as in the following cases.

Case 1.—J. S., male, æt. 23, an army cook with the Waziristan Field Force, admitted on 14th July, 1923, in a state of absolute mutism with a facial expression of defiance and a tendency to be violent when interfered with. He was resistive and refused to comply with simple requests, such as asking him to show his tongue, to sit or stand up. He was in this state for 4 months prior to admission. He was given thyroid extract grs. v., *b.d.* for 9 days at the end of which he was not so resistive as before, showed more voluntary activity and responded readily by action. At this stage suggestion and persuasion were tried and a month and six days after admission he spoke to the hospital attendants, became cheerful, active in his habits and answered questions readily. He had a clear consciousness and correct memory of all events during his illness. After discharge from hospital he joined his old post.

Case 2.—N. B., female, æt. 20, admitted on 21st January, 1924. Speechless, holds her mouth tightly closed, remains in any position that she is placed in, had to be forcibly fed, and smiled occasionally without any reason. Her previous history was that she was hallucinated and incoherent for three months before admission and then became mute and resistive. Under suggestion her resistance to external stimuli was gradually overcome, her cataleptic rigidity disappeared and she began to walk about, accepted food readily, took interest in her surroundings, and indicated her wants in writing. Three months after admission she began to speak freely and was discharged from hospital. She is reported to be getting on well in her home.

A point of interest to general practitioners is that some of these cases in their incipient stages may be mistaken for hysteria or neurasthenia. It must be borne in mind that dementia præcox may supervene on a previous hysterical or neurasthenic state. A writer in a recent issue of the *Lancet* emphasises the importance of keeping the possibility of a psychosis in mind when a young adult is seen with neurasthenic or hysterical symptoms. The two cases recorded above would at first sight appear to be hysterical, but

unlike the hysteric, there was a definite air of unconcernedness to environment with a marked negativistic tendency in each of these patients.

In this connection it may not be inappropriate to allude to a tendency prevalent among the public—and shared in by some medical practitioners—of dubbing any case of disordered conduct as hysterics, especially if it happens to be in a female, even when definitely insane symptoms are manifested. It is needless to point out the danger of glossing over a serious disease by calling it simply hysterics and treating it as such. It may be consoling to the relatives to know that the patient has nothing but hysteria, but a medical man has his primary duty towards the patient and a proper evaluation of the signs and symptoms by a careful examination and application of the appropriate treatment in the early stages should be his aim. A great majority of the dementia præcox patients in a mental hospital are of the "hebephrenic" type. They are shy, seclusive and solitary; they regard with indifference the events of life. They are taciturn, constrained, withdraw themselves and avoid people. They are cool and indifferent to their relatives and sometimes distinctly hostile to them.

Treatment.—In institutions for the insane, occupation of some sort helps greatly to divert their minds from impulsive acts. In fact, in the opinion of the writer, one cannot provide too much occupation for them. At first the idea of any definite work is resisted by these patients, but with persuasion they could be got round and the effect of systematic work is seen in the improvement in their physical condition and corresponding increase of mental stability. They give up their destructive and dirty habits and in course of time behave well and some of them who have been discharged from hospital have shown sufficient interest in their homes and relatives and a clear outlook on life. Relapses occur in many cases, both in hospital and after discharge therefrom. In one case a return to her home brought on, in a female patient, a very violent form of excitement, the like of which was not seen during her two years' stay in the asylum.

It is important to recognise that an eruption of impulsive acts which initiates this disease is generally due to environmental handicaps, and a careful inquiry into the past history of the patient and his present relationship to the world around him would furnish a clue to the means to be adopted in dealing adequately with his disorder at the onset. Treatment in such cases may have to be applied not only to the patient but to his relatives as well in the shape of sound advice regarding their dealings with him. It is the latter that have to adapt the environment to the patient when he has failed to adapt himself to it. Ungovernable temper, extreme self-consciousness, excessive sensitiveness or emotional instability are some of the points to be noted in prospective cases of dementia præcox and suitable means of prevention should be adopted, for preventive

medicine with which every practitioner is seriously concerned should also include mental hygiene.

Only the extreme types of dementia præcox are found in a mental hospital. A good many mild forms of the disease remain outside and pass through life unnoticed, fighting a hard battle in life, which, had they been early diagnosed and treated would perhaps have been rendered more happy individually and more useful to society.

EXPERIMENTS IN AIR EMBOLISM.

By A. R. D'ABREU, F.Z.S., I.M.D.,
Assistant to Civil Surgeon, Lahore.

MANY articles have appeared from time to time in the *Indian Medical Gazette* and other medical journals, on the experiences of various medical men, of the introduction of air emboli into the veins, as also have discussions on their danger to life or otherwise. The description of the following experiments on cows and bulls may therefore not be out of place and are given for what they are worth.

I was at the Lawrence School, Ghora Gali, as Resident Medical Officer from January 1922 to June 1923, and during this period one of my routine sanitary duties was to inspect the school slaughter house, where almost every second or third day two cows or young bulls were killed by the school butcher to provide beef for the school children and staff. The butcher was a Mohamedan and the usual method of slaughter was to pass a rope around the legs, then to throw the animal suddenly by twisting the head and neck round by the horns while a second man tripped the legs with a strong bamboo, and once down, the animal would be kept on its side, the four limbs secured tightly together and the twisted neck cut down upon with a sharp knife (*halal*) until the carotids on the two sides were severed and also the windpipe and gullet. The wound in the neck would now be made to gape by holding the head well back until the great vessels had emptied themselves and life became extinct. This knack of twisting the neck and keeping it so, rendered quite powerful animals absolutely harmless and motionless on the ground for the subsequent deliberate use of the knife.

I had a little while previous to this been making certain observations on these animals in a different direction and as so much experimental material was available the thought struck me to try the effect of air emboli to produce death in the hope of bringing it about with less torture, as to any onlooker the above process was somewhat cruel and painful.

The following experiments were therefore tried. I will first mention certain difficulties which I encountered. Direct puncture through the skin into the vein (which one does

so easily in human beings) is difficult, or at least was so in my inexperience of this operation on animals, and the vein needs to be dissected out. It is difficult to get directly through the skin (which is much too tough to pierce) into a cow's veins and at the same time use the precision which is required in these little operations. Big as the veins may appear against the skin, once punctured and manipulated they tend to collapse easily, so that a careful effort should be made to enter the vein with the needle at the first attempt. Incising the vein and tying in a cannula increase the difficulty and lead to quicker collapse of the vessel but a large quantity of air is more easily injected and with greater certainty. At first veins on the legs were chosen but were not always found to be prominent enough, and besides, a sudden though even very limited jerky movement, with the weight of a bull or cow behind it, usually meant breaking a needle. Next, the neck veins were tried (the jugular veins are used by veterinary surgeons) but these were also unsuitable and the skin too thick over them, besides having to contend with the awkward twisted position of the neck already alluded to. Finally the large prominent veins on the belly were selected and, though very mobile under the skin, the skin over them was thin enough to be dissected easily and quickly to get at these vessels. This proved satisfactory under the circumstances. I was single-handed and without any elaborate steadying apparatus; I daresay with the help of a veterinary surgeon better sites and methods might have been suggested for vein puncture.

Experiment No. 1.—Having dissected out a vein, 10 c.c. of air was injected gradually by puncture into the lumen of the vessel with a 20 c.c. serum syringe. This produced no symptoms in the animal.

Experiment No. 2.—The same procedure was adopted as in experiment No. 1 but 20 c.c. of air was injected. No result followed and the animal appeared quite unaffected.

Experiment No. 3.—The vein was entered and 20 c.c. of air was injected with one sharp movement home of the piston in the hope of producing a continuous column of air in the vessel. There was no apparent effect on the bullock after this and so the syringe was quickly removed from the needle (which was left in the vein), the piston drawn up, and another similar brisk injection of 20 c.c. of air given. The expected death of the animal still seemed remote and so the syringe was removed from the needle for a third 20 c.c. injection of air, but as some blood had entered the barrel and made movement of the piston difficult there was a little delay in re-fixing the syringe to the needle, which had by now

become blocked with clot. After this experiment the conclusion was naturally arrived at that a syringe with a much greater capacity was necessary. An ordinary 4-oz. glass urethral syringe was tried but as the piston was defective sufficient pressure was not available due to slight leakage in the process of forcing air through the needle or cannula, although it could be made to work with the latter as less pressure was necessary. Resort was therefore had to an ordinary 4-oz. metal ear syringe with a true-fitting piston and a short rubber connection leading to a cannula. The glass urethral syringe was eventually used in the last experiment but one—with a positive result—as will be seen later.

Experiment No. 6.—Having been defeated out and a Roger's cholera cannula carefully tied in; this was attached to a rubber tube leading to a 4-oz. glass urethral syringe. Four ounces of air was injected quickly with no visible effect on the cow. This quantity of air in all probability did not wholly enter the vein as I discovered later that the piston was not satisfactory, and far from true-fitting, as explained above.

Experiment No. 5.—On this occasion a cannula was tied into the vein as in the previous experiment and four ounces of air was emptied into it with the help of a ear syringe. This had no immediate effect and so the rubber connection was removed, the piston pulled up, and a further charge of four ounces injected. The animal now became somewhat restless and this resulted in the cannula being dislodged from the vein, but death nevertheless did not take place.

Experiment No. 6. Having been defeated so often in arriving at the lethal dose of air which should be injected into the vein of a cow or bull the following experiment was made. I acknowledge it was very unscientific as the volume of air was not measured and the quantity used can therefore only be guessed at roughly. As before, a cannula was tied in and from it a rubber tube was connected to the barrel of a 4-oz. urethral syringe from which the piston had been removed. To the open upper end of the barrel of the syringe I applied my lips and steadily blew air into the vein. A low gurgling sound was heard going up the vein and after about 10 to 15 seconds of steady blowing the animal got restless and then to all appearances became suddenly unconscious; the eyes glared and were turned upwards, the respiration became spasmodic, the body and limbs turned rigid and death ensued. I should imagine I blew a pint and a half or more air into the circulation in this attempt.

At the postmortem examination immediately after this experiment the right auricle and

ventricle were found full of an admixture of air bubbles and blood, the former varying in size from $1/16$ to $1/3$ of an inch in diameter, and the roots of the superior vena cava, inferior vena cava, and pulmonary artery were similarly filled. The left side of the heart was empty except for a trace of blood with very occasional fine air vesicles in it, but these may have been admitted in the process of cutting with the soiled knife already used on the right side. No consolidated clot had yet formed around these air globules. The whole appearance was frothy and there were more fine bubbles than large ones.

Experiment No. 7.—As the last experiment gave no exact idea of the quantity of air required to produce death I finally decided to try one further experiment. The death of the cow in this case was produced under rather amusing circumstances and not, after all my labour, exactly from embolism.

By the Mohamedan religion it is required that all animals whose flesh is intended for consumption should be killed by cutting of the neck, i.e., "*halal*." This religious point in the killing did not affect experiment No. 6 as the Mohamedan butcher had, unintentionally on my part, been taken unawares but, however, he had my genuine apologies when I discovered my mistake.

For this experiment I secured a large motor pump with a 24-oz. barrel and had a well-fitting metal piston made for it. The same procedure was adopted as in the previous experiments. The large inrush of air produced a slight gurgle in the veins and then as the end of the injection was nearing, the animal commenced to be somewhat restless, the respiration became jerky, the limbs stiffened and undoubtedly death would have followed. But the butcher's anticipation at this moment was surer than mine, from previous experience,—for I suddenly found the animal being shaken to and fro by someone and on lifting my gaze from the site of operation I found "*halal*" had commenced to be performed before the death I was in process of producing by air embolism, had been completed.

On opening the heart of this animal about twenty minutes later the left side was found empty and the right side was practically so and only contained a little frothy blood adhering to the posterior wall of the ventricle. The large vessels appeared to have drained themselves through the neck wound. All the other five animals experimented with were slaughtered by the butcher after an hour or so but no air emboli were found in the heart or large vessels.

Discussion.—The results of the following table experiments are interesting and will therefore be mentioned first. When air is injected into the bottom of a tall open vessel containing a mixture of glycerine and water,

of the specific gravity of the blood and resembling it in viscosity, part of the air splits up into fine globules and becomes disseminated through the fluid while other bigger bubbles rise to the top and either remain on the surface of the fluid or if blown up rapidly, leave it. The fine suspended bubbles after a little while also gradually rise to the surface. If this experiment is tried with glycerine, which is of considerably higher specific gravity than blood, part of the air breaks up into very fine globules which remain suspended for a much longer time before finally rising to the surface, the larger bubbles also rising to the surface but somewhat slower than with the previous fluid. The behaviour of air emboli in an artificial circulation made up with an ordinary Higginson's syringe with glass and rubber tubing of even calibre interspersed in its course and with the use of the above mixture, with a specific gravity of 1056, is as follows:—

The glass tubing in the apparatus showed all changes very clearly, and in all, twelve feet of combined glass and rubber tubing was used to give plenty of circulating room. The apparatus was laid on a table (ordinary lying position of a patient) and the fluid circulated; then the rubber tubing representing the vessels was entered with a serum syringe needle and air injected very slowly. However slowly the air was injected each downward movement of the piston showed one discrete and visible bubble of air admitted to the circulation, so that at the point of injection and a little while after, each injection—or successive injection as it were—caused a bubble or bubbles which remained entire, and there appeared no tendency for this air to break up into smaller bubbles on entering the moving fluid in the tubing. Directly these bubbles came round into the syringe bulb they emerged as many minute globules which were in turn broken up still smaller each successive time they passed through the bulb and were subjected to the churning or pressure action of it. If a similar state of affairs occurs in the human circulation then it is possible that in the right heart all small air emboli admitted in error soon get broken up and on reaching the lungs must be partly absorbed at any rate.

In the same experiment when 10 c.c. to 20 c.c. of air is injected rapidly it enters the circulating fluid in large and small bubbles indiscriminately. The large globules are an inch or more long and on entering the bulb they break up, but, nevertheless, many large air spaces run round the circulation for a fairly long time and are not eventually broken up to any fine degree. To imagine this process going on in a patient's circulation suggests immediate danger to life. The tubing of the Higginson's syringe and the glass and rubber

connecting tubing used was 3-8ths of an inch in diameter, but if some rubber tubing the size of a No. 6 or No. 7 Jaque's catheter is let in then the bubbles of air are broken up into finer emboli but the rate of the circulation is naturally slowed if the same squeezing power is used on the bulb.

In the above experiments, during the suction of the syringe, or diastolic period, there was a little breaking up of the air bubbles noticed in the tubing, but to no great extent as compared with that during contraction when in the bulb itself. With glycerine (specific gravity 1260) and with mixtures of it with water (of a higher specific gravity than the blood) it is very difficult to get the circulation to go round and much force is required on the bulb, but the breaking up of the air bubbles is more complete, particularly when only a few are admitted. The question arises as to what happens to this air on entering the circulation. It is undoubtedly removed or absorbed by the blood during circulation as these little accidents must occur daily; yet no adverse reports come to hand. Some writers have suggested that there is probably a rapid breaking up of the air bubbles by a churning process of the circulation, especially so in the heart itself, and which thus get quickly absorbed. The splitting up in the heart apparently occurs, judging from the above trials. Presumably, of course, some of the oxygen at any rate is soon taken up by the blood while in the veins, as we know how quickly the tarry fluid from these vessels changes its colour even outside the body when in contact with the atmosphere for a short time.

Quite large-sized air emboli have been found in the heart at autopsies in cases where there have been wounds of the lungs, and these globules have been coated with firm clot. A recent writer has also attributed gangrene of the intestines to similar air embolism in these cases. Whether a failing circulation retards the disintegration of large air emboli and their subsequent absorption and leads to the deposit of thrombus around them is a point naturally worth bearing in mind. It is known how quickly blood clots when in contact with the air; so also when a circulation is weak and slow, would we expect the possibility of the same blood, being in contact with the air in the vessels for a longer time, tending to coagulate around it. Then there is also the possibility of their formation a very short time before and after death, with the stagnation of the blood stream, as the findings have after all only been postmortem.

If one visualises the circulation in the tail of a tadpole, with the corpuscles as air emboli, it can easily be imagined how thrombus is likely to form with a hesitancy of these air corpuscles against the vessel walls, as the

circulation is retarded at the gradual approach of death. In diseases where the specific gravity of the blood rises and the circulation is weakened or slowed, air embolism would be risky, though perhaps the entry of a very small quantity of air should be better broken up in the heart due to the increased viscosity.

The pulse rate of an ox is 45 per minute, so that the human being with a pulse rate of 70 to 80 per minute is at some advantage compared with these animals if it is possible that the velocity of the circulation—which, by the way, is actually much slower than the pulse wave—helps to prevent thrombus forming around the air. The pulse rate of the dog is about 75 to 90 per minute and, of all domestic animals, the nearest to man. It is just possible that its circulation rate of 250 mm. per second with the systole and 127 mm. per second in diastole (approximately 10 inches and 5 inches per second respectively), would about roughly correspond with the human circulation. Supposing that the blood takes 15 to 20 seconds or probably much more from the time it leaves the heart to its return to that organ (jugular methylene-blue test), and granting an average of five minutes as the period taken for blood to coagulate outside the body, it would be reasonable to expect that a few bubbles of air, admitted by chance, would be of very small consequence as they will have travelled around in the circulation (if this does happen) fifteen times in five minutes and will thereby have been given plenty of time to be churned and broken up into very small bubbles and to get absorbed. From physiological experiments we know that the velocity of the blood-flow is greatest in the large arteries; in the capillaries it varies from 0.5 to 1 mm. a second, and in the large veins it runs at about half the rate as compared with the arteries. These facts give the expectancy of thrombus formation with more certainty in the capillaries and veins. In those diseases where there is thrombosis these are the more common sites. On the other hand, arriving at the capillaries the air would have reached a very fine state of division, so that its absorption in this position is more feasible.

Physiologists are somewhat divided in their opinion as regards the coagulation of the blood, but the prevailing idea is that thrombin is brought about from thrombogen and calcium salts by the activating material thrombokinase which is present in most of the tissues of the body and is particularly produced from the blood-platelets which are only supposed to be formed after the shedding of blood and its contact with a foreign surface. It is known that the blood of birds contains no platelets and will not clot unless it comes in contact with the tissues or tissue extract is added to it, so that in all probability the circulating blood

contains no thrombokinase. In our experiments the question arises as to whether the admission of air into a vein produces a condition in the vessels akin to the shedding of blood and contact with a foreign substance. If so, then there must be a subsequent production of blood-platelets and thrombokinase in vitro resulting in clot, which will mean that any quantity of air admitted into the circulation is fraught with this danger. On the other hand, to help the outcome, we know the affinity hæmoglobin has for oxygen and that blood-plasma might dissolve nitrogen, carbonic acid and oxygen,—all constituents of air,—and that phagocytosis of the white blood corpuscles would come into play, so that in the case of a few small bubbles of air entering the circulation the blood itself probably has the power to deal with them.

The foregoing points would lead one to suppose that with an active circulation the entry of a few small air emboli is really a negligible quantity.

During my personal experience of the past fifteen years with intravenous medication I have several times accidentally admitted a few air bubbles into the circulation, some of which were quite large, but remember no ill effects resulting. In my earlier days I had a great dread of them, having been warned of the danger by my teachers and later by colleagues, of the entry of even the smallest bubble of air into the circulation, but I have since found this theory to be quite erroneous. In passing, though, I will mention certain bad results which I have experienced with intravenous injections although they do not really bear on the subject.

Some years ago I remember a patient developing paresis of the right arm and another developing slight paralysis of one side of the body; both occurred after an intravenous injection of salvarsan. These two cases soon recovered and were in all probability due to blood clot. I was absolutely certain that no air had entered the vein, but what I had noticed was that as the needle entered the vein there was a very pronounced inrush of blood into the windowed tubing attached to it, and that as the injection was started this blood, which must have already clotted, was naturally driven back into the circulation. In the case of intolerance and severe reaction with certain preparations it is advocated by some to desensitise the blood *ex-corpore* by allowing this regurgitation of the blood from the vein into the apparatus or syringe, and then after some minutes to inject this mixture of venous blood and solution. After the above experience I have always taken the precaution to have the torsion on the upper arm removed as quickly as possible once the vein is entered, as I feel that no two bloods behave alike as regards clotting once they leave

vessels. In another-patient, with resistant malaria, who tolerated quinine quite well, I gave an intravenous injection of quinine hydrochloride. This was soon followed by curious blindness in one eye, which lasted for about 48 hours. It was said by some to be an idiosyncrasy to quinine. No air bubbles had entered the circulation but a fair amount of blood had come into the syringe, and was passed back into the vein. This was the patient's second injection, the first having caused no untoward symptoms. At the third injection care was taken not to admit blood into the syringe and the process was completed without similar after-effects. I leave my readers to decide whether this was due to blood clot or not.

Conclusions. A few small bubbles of air injected into a vein at a slow rate are apparently harmless, and a like remark would also appear to apply to a small continuous column of air, judging from the results of these experiments. In the last experiment 24 ounces of air was sufficient to produce the death of a bull weighing approximately 500 lbs., so that a man weighing 10 to 11 stone would proportionately take about 6 to 7 ounces as the lethal dose. Rabbits succumb very easily to air embolism but they are somewhat delicate and susceptible rodents, and as human beings we might be similarly qualified, as our endurance can hardly be compared with the beasts of the field on whom the experiments were tried. Hence the lethal dose would in reality probably be less than 6 or 7 ounces. On the other hand, the velocity of the circulation and pulse rate (45 per minute) in oxen are both slower than in man, and the specific gravity of their blood—which is 1060 or slightly more—is higher than in man, the three being qualities likely to give a greater susceptibility to the effects of air emboli although their endurance may be greater than man's.

The first noticeable symptoms were produced in experiment No. 5 when eight ounces of air was injected. Assuming this quantity to be the dangerous limit for the animals used, then, working it out proportionately on weight, a volume of 2 ounces and 2 drams would be unsafe for man. An error of this magnitude could only occur from very gross neglect.

Blood of a thicker consistency, i.e., of a higher specific gravity than the normal of 1056, must flow through the vessels with difficulty and be more prone to clot around air globules. If, therefore, in disease the specific gravity of the blood—for any reason—goes up with a retardation of the flow, then the admission of air into the veins should be carefully guarded against. In those diseases in which the coagulability of the blood is increased these precautions should also be

taken. When severe hæmorrhages have taken place the blood coagulates quicker than normally, and in these cases also the entry of air during intravenous transfusions should be especially excluded. In such cases, before any quantity of fluid has been transfused, a large air embolus entering the feebly-acting right heart would be likely further to embarrass its action, causing clotting and death, which might easily be put down to the original progressive collapse. In anticipation of these accidents with air emboli of large size some antidote in the form of an injection for immediate use, to reduce the coagulability of the blood, suggests itself.

TREATMENT OF SOME ABDOMINAL CONDITIONS WITH INFLATION OF OXYGEN GAS.

By RAJINDER S. GREWAL, L.M.S. (S'pore),

*Civil Assistant Surgeon,
Civil Hospital, Maymyo, Burma.*

TREATMENT of a cold abscess by filling its cavity with oxygen after evacuation of pus had been some time back warmly advocated by Lieutenant-Colonel E. R. Rost, L.M.S.; the results attained by him were by no means unsatisfactory but he did not try the value of oxygen in certain abdominal conditions. It was with this intention that the experiment of inflation of the abdomen with oxygen was undertaken. During the past few months this method of treatment has been used with great success at the Civil Hospital, Maymyo, in a few diseases of the intestines, peritoneum and mesenteric glands.

First a case of tubercular diarrhoea which had not been amenable to any form of treatment, including emetine and astringents, was treated with inflation of the abdomen with this gas. The result was very encouraging and it made us extend our investigation further in the domain of abdominal diseases limited to infections in which tubercular bacilli have been the causative agent. The results thus far obtained have been highly successful and gratifying, therefore they are published for the information of the medical profession with a hope that they will report the value of this gas in similar ailments after giving a fair trial to this method of treatment.

INDICATIONS OR DISEASES IN WHICH THIS TREATMENT PROVES BENEFICIAL.

1. *Tubercular Diarrhoea.*—This form of diarrhoea is most difficult to treat; in some cases the diarrhoea cannot be checked. When pills of plumbi subacetate, emetine and astringents have no effect then the treatment by oxygen should be resorted to.
2. Another condition in which this treatment proves a success is chronic tubercular peritonitis.
3. It may also be undertaken in cases where free fluid in the peritoneal cavity is present due to chronic tubercular peritonitis.
4. The last, but not least, is "tabes mesenterica"—a disease not so commonly met with.

PREPARATION OF THE PATIENT BEFORE OPERATION.

General.—The patient is kept confined to bed for a day or two previous to operation. Ordinary nourishment to which the patient is accustomed is allowed. In cases of tubercular diarrhoea solid diet should be withheld.

Local: Preparation of the skin.—The skin of the abdomen is well scrubbed after shaving the hair, if any, with a solution of soap and rectified spirit. Then the solution is washed off with warm water and the skin dried. Next the skin is painted with a solution of Hydrarg. Biniodide:—

R	Hydrarg. Biniodide Rubri.	..	grs. xvi.
	Pot. Iodide	..	grs. xvi.
	Spirit Methylated	..	ozs. xii.
	Aqua	..	ozs. xviii.

And finally sterilised dressings are put on and a "many-tailed" bandage applied.

A hypodermic injection of $\frac{1}{4}$ gr. morphia and 1|100 gr. atropine is given an hour before the appointed time for the operation.

TECHNIQUE OF THE OPERATION.

The technique of the operation may be divided into four different stages:—

1. The anæsthetizing of the skin.
2. The opening of the abdomen.
3. Inflation of oxygen gas.
4. Closing of the abdomen.

1. *The anæsthetizing of the skin.*—The site of incision is anæsthetized with one of the local anæsthetics in common use, e.g., cocaine, novocaine, quinine and urea, or any other suitable drug. In our cases apothesine and adrenalin was the drug of choice and it was found that a 2-per cent solution gives much better results than a 1-per cent solution. The solution is prepared by mixing 1 tablet (apothesine gr. 1|3 adrenalin 1|25000 gr.) in 1 c.c. of water or normal saline. The usual amount of solution required for a case varies from a half drachm to two drachms, but on the average one drachm solution is sufficient. The solution is injected into the middle line with a hypodermic syringe or Barker's local analgesia syringe. An interval of five to ten minutes is observed before commencing the second stage of the operation.

2. *The opening of the abdomen.*—The second stage begins with the incision of the skin and ends with the insertion of a purse-string suture round the peritoneal opening.

A small incision 1 in. \times 1½ in. long is made in the middle line midway between the umbilicus and symphysis pubis; fascia and muscle is cut through and muscles separated by blunt dissection and peritoneum reached. The peritoneum is then caught between two forceps, opened and snipped and a purse-string suture applied round this opening. Care should be taken to prevent the peritoneum from falling into the abdomen.

3. *Inflation of oxygen gas.*—Now a tube conveying oxygen is thrust into the abdomen and the

suture ends tightened around it so as to prevent the leakage of gas. When it is full a general discomfort is complained of by the patient and the distension is visible. (One of our patients remarked "Stop! my belly is full.") The tube carrying the oxygen is withdrawn and the purse-string suture tightened and tied.

4. *Closing of the abdomen.*—Having inflated the abdomen with oxygen the wound is closed layer by layer; a few interrupted skin stitches or Michel's clips are applied, the dressings finally put on and the abdomen bandaged.

APPARATUS REQUIRED.

The apparatus required for this operation is very simple and can be easily made at most of the district hospitals where an oxygen cylinder is available. It consists of an oxygen cylinder and an I.R. tube leading from its outlet to the bottle of hydrogen peroxide, at the end of which a small glass tube is inserted. The tube carrying the oxygen dips into the hydrogen peroxide; the oxygen is thus washed and again carried through a tube which leads from the hydrogen peroxide bottle just above the fluid surface and ends where the glass connection is. Another I.R. tube which is previously connected with a brass tube or a sterilised nasal tube is then connected with the tube coming from the hydrogen peroxide bottle by means of a small glass connection. The flow of oxygen is regulated by the key; it is essential to regulate the flow as a sudden rush of oxygen into the bottle generally pushes the corks out of the bottle with a tremendous noise resulting in unnecessary delay which is undesirable when the patient is on the table.

LENGTH OF TIME REQUIRED FOR AN ABDOMEN TO REGAIN ITS NORMAL POSITION.

Without the proper criterion to measure the amount of oxygen pumped into the abdomen it is difficult to ascertain the exact period required to dissolve a certain amount of oxygen, but in our cases it was noticed that in most instances a fully distended abdomen regained its normal position within 12 to 36 hours.

Rationale of the Treatment.—It is difficult to advance a theory as regards the way in which oxygen brings about a cure. Whether it is due to its oxidising property or some other property remains to be investigated.

ADVANTAGES OF THE OPERATION.

1. It can be done in subjects who have lung complications and also when the use of chloroform is not safe.
2. Very few instruments are required.
3. There is no danger.
4. It can be done even in small hospitals.
5. Results are good.

My thanks are due to Lieutenant-Colonel L. E. Gilbert, C.I.E., M.D., D.P.H. (Lond.), I.M.S., for permitting me to publish the following cases:—

Case 1.—A Hindu male, aged 20, was admitted into hospital on 30th March, 1925. On examination he was found to be suffering from pulmonary tuberculosis and tabes mesenterica. He was operated upon on 3rd April,

Summary of the Cases.

Number.	Age.	Sex.	Disease.	Date of operation.	Result.	REMARKS.
1	20	Male.	Tabes mesenterica ..	3-4-25	Improved ..	Later died of pulmonary tuberculosis.
2	40	Male.	Tubercular diarrhoea ..	30-7-24	Apparently Cured
3	8	Female child.	Tubercular peritonitis ..	27-1-25	Greatly improved	Apparently well.
4	42	Male.	Tabes mesenterica ..	15-4-25	Improved ..	Returned to work.
5	23	Male.	Tubercular peritonitis ..	13-3-25	Greatly improved	Invalided By permission of Captain H. Williamson, F.R.C.S.E., I.M.S.
6	20	Male.	Tabes mesenterica ..	18-3-25	Greatly improved	

1925, and oxygen was given intra-abdominally. The mesenteric glands which were palpable became small but the patient died later from the effects of general tuberculosis.

Case 2.—A Hindu male, aged 40, was admitted into hospital on 5th July, 1924. On examination it was discovered that he suffered from diarrhoea which was very obstinate and not amenable to any drug treatment. On further investigation it was found to be of tubercular origin. He was operated upon on 30th July, 1924, and oxygen was inflated into his abdomen by Lieut.-Col. L. E. Gilbert, I.M.S. Soon after the operation he began to improve, the stools became fewer and fewer till finally he was cured and discharged from hospital on 26th August, 1924.

Case 3.—A Hindu Tamil, female child, aged 8 years, was admitted into hospital on 7th January, 1925, in a very emaciated condition with a hectic temperature, signs of pulmonary tuberculosis and chronic peritonitis with a small amount of free fluid in the abdomen. Oxygen was pumped into her abdomen on 27th January, 1925, after which she was able to walk about, the fever subsided, appetite increased, and her general condition improved. She was discharged cured, on 8th March, 1925, and is now a frequent visitor to the hospital.

Case 4.—An Indian Hindu male, aged 42, was admitted into hospital on 13th April, 1925, with tabes mesenterica and general debility. On 15th April, 1925, he was given oxygen intra-abdominally. Three days later his fever subsided, appetite increased, and general health improved. He gained in weight and is now well and back at work.

Case 5.—A European male, aged 23, was admitted into hospital on 21st February, 1924, for the treatment of enlarged glands of the right groin and pyrexia. The temperature continued and the glands became soft and finally had to be aspirated and yellow pus drawn. His blood was examined thrice for malarial parasites with negative results. The case was diagnosed as one of tubercle of the lung and peritoneum. During his stay in hospital he had an attack of hæmoptysis and complained of general pain in the abdomen which was soft and doughy. He had seven motions of a pale colour on 12th March, 1924. On 13th March, 1924, he was operated on and oxygen was inflated into his abdomen. On 16th March, 1924, his temperature became normal, pulse improved, and—above all—abdominal pain and diarrhoea ceased. After this he continued to improve till he was discharged on 15th July, 1924, and later invalided.

Case 6.—A Burman male, aged 20, was admitted into hospital on 17th December, 1924. On examination the mesenteric glands were found to be enlarged. On 18th

March, 1925, oxygen was inflated into the abdomen by Capt. H. Williamson, F.R.C.S.E., I.M.S. On 30th March, 1925, his general condition distinctly improved and he was then invalided.

ACTION OF DISINFECTANTS ON MICROBES: AN INTERESTING PHENOMENON.

By Dr. H. GHOSH, M.B.,

Bengal Immunity Research Laboratory, Calcutta.

IN the course of our experiments on acclimatisation of bacteria to disinfectants we observed a very interesting phenomenon. We began our work to find out whether by increasing the time of contact of bacteria and disinfectants the rate and extent of growth of the former declined or increased. During the course of this work we found that certain bacteria showed some growth after one hour of contact with a disinfectant but produced no growth after 3 to 5 hours of contact. After 24 or 48 hours of contact, however, a few colonies appeared at first but gradually the number increased as the time of contact was increased. Before entering into further discussion on this phenomenon and its explanation we should describe the technique which we followed.

Technique.—A twenty-four hours' culture of a certain bacteria in broth was taken and different dilutions of a certain disinfectant were made in that broth culture. These were then kept in the incubator and after 1, 3, 5, 24, 48, 72 and 96 hours respectively, 0.1 c.c. from each of the dilutions was inoculated on to an agar plate. These plates were examined after 24 and 48 hours of incubation and colonies identified and counted. In our experiments we used *B. pyocyaneus*, *B. proteus* (X19), *S. aureus*, *B. coli*, *V. cholera*, *B. dysentericus* (Shiga) and the disinfectants used were iodine (in KI) solution, potassium permanganate, optochin and sublimate.

Experimental Findings.—We observed in this way that up to a certain concentration of the disinfectants the microbes were actually killed, but in certain dilutions (vide curve), while there was

absolutely no growth whatsoever up to 5 hours of contact, colonies appeared after 24 or 48 hours of contact. The number at first being a few increased as the time of contact was increased up to a certain limit. It was also noticed that in 1 to 5 hours of contact there were only a few colonies which, as the time of contact was allowed to increase, became innumerable. In the latter case it was no doubt due to acclimatisation of the microbe.

In the accompanying charts we have indicated the dilutions in which the growth increased from a few to innumerable colonies or from none to many. To determine the phenomenon of acclimatisation we made dilutions of the disinfectants in bouillon of the highest concentration in which there was growth, and then inoculated the acclimatised bacteria in one tube and the non-acclimatised bacteria of the same strain in another. We repeatedly found that there was growth of the acclimatised bacteria, whilst there was absolutely no growth of the non-acclimatised bacteria.

Explanation of Charts.—**Chart No. I.**—It can be seen that in chart No. I. *B. pyocyaneus*, in dilutions of 1/2000 of iodine, shows very slight growth after 1, 3, or 5 hours of contact, but after 24 hours the growth increases. In the case of

CHART I.

N.B.—Up to dilution 1/500, staphylococcus and *B. proteus* die quickly. *B. pyocyaneus* does not grow up to dilution 1 in 1000.

R. proteus (X19) there is absolutely no growth after 1, 3, or 5 hours of contact, but in dilutions of 1/1000 of iodine there is full growth after 24 hours. Almost similar results are found in the case of *S. aureus*.

Chart No. II.—*B. proteus*, in dilutions of 1/100 of permanganate, does not show any growth after 3 or 5 hours of contact, but after 24 hours of contact colonies begin to appear. Similar results are found in the case of *V. cholerae*. *B. coli* shows a few colonies at first, but after 24 hours there is abundant growth. *B. dysentericus* (Shiga), however, resists the action of disinfect-

CHART II.

ants up till 48 hours of contact, but after that period dies out totally.

Chart No. III.—With optochin, in a dilution of 1/1000, *V. cholerae* and *B. proteus* show growth after 24 and 48 hours of contact respectively, while there is no growth after 3 and 5 hours of contact. *B. dysentericus* (Shiga) is totally killed

CHART III.

B. shiga — No growth in stronger dilutions than 1 in 1000. Growth rich in more diluted solution.
B. coli — Growth in 1 in 500 dilution is similar to that of *B. shiga* in 1 in 1000.
V. cholerae — Stronger dilution than 1 in 1000 gives no growth.

B. proteus — Same as *V. cholerae*.

by the above dilution of optochin. In the case of *B. coli* the growth diminishes up till 24 hours of contact, but after that period there is an increase of growth.

Explanation of the Phenomenon.—The interesting point in the experiment is that the microbes seem to be killed by a certain dilution of the disinfectant up to the first 5 hours of contact but divide and multiply when placed in fresh medium

after 24 hours. We haven't any means by which we can find out the state of the microbes in the disinfectant solution during the period when they are unable to multiply, consequently we are unable to put forward a definite explanation. We may be permitted, however, to suggest an explanation that probably most of the microbes are killed by the disinfectant effect of the chemicals used; others more resistant get attenuated and lose the power of division and multiplication for a certain period,—during which time they show no growth even when placed in fresh medium. This period may be called a period of shock to the bacteria. Later, as the time of contact increases, this condition of shock passes off and they adapt themselves to the environment and begin to multiply again, and on inoculation into new medium show abundant growth.

"STIBOSAN" (VON HEYDEN "471") IN PRIVATE PRACTICE.

By SUDHIR KUMAR DAS, M.B., D.T.M. (Cal.),
Calcutta.

WHILE I was a student in the Calcutta School of Tropical Medicine I was much impressed by the results obtained from the use of von Heyden "471" in the treatment of kala-azar in the wards of the Carmichael Hospital for Tropical Diseases.

With my former experience with other antimony compounds I can say that "471" is much better, perhaps the best, of all antimony compounds that are now available in the market.

I have put the results I obtained in my cases into tabular form for the convenience of readers; the points that struck me most with regard to the compound are:—

(1) The rapidity with which it checks the fever. In my series of cases the average number of injections required to check the fever was three.

(2) The short duration of the treatment; thus the patient is invalided for a short period only.

(3) The rapid reduction in the size of the spleen. The spleen at first becomes thinned out, then diminishes in size, and from the fifth injection reduces very rapidly.

(4) No untoward effects noted. In my cases no vomiting occurred after injection, not even after meals, and no pulmonary complications occurred.

In all my cases the clinical diagnosis was confirmed by the aldehyde test which was strongly positive in every case. The cure* of the cases is judged by the fact that since the course of injections was finished none of them have had any return of fever. After the injections they rapidly gained weight.

TABULAR STATEMENT OF THE CASES.

Case No.	Age.	Sex and religion.	Condition at the beginning of treatment.	Duration (in months) prior to treatment.	No. of injections to final disappearance of fever.	Total No. of injections given.	Total amount (in grms.) of compound given.	Period of treatment (in days).	SIZE OF SPLEEN.		Period (in months) elapsed since last injection.	Present condition.
									At beginning of treatment.	At completion of treatment (in inches below costal margin).

H. F. = Hindu female.

I decided to try this compound on private patients so asked Dr. Napier for a quantity of it; he very kindly supplied me with a sufficient quantity to treat three patients. Later on I obtained the drug direct from the firm of von Heyden; it is now available from their agents in India,—Messrs. Allen & Hanburys.

Two of my cases deserve separate mention here. In case 1 the patient had been suffering from piles, heart trouble (a systolic bruit in the mitral

* Spleen puncture is not popular in private practice so this method of testing cure was not attempted. Blood culture, I am told by Dr. Napier, is quite valueless as a means of testing cure.

area), and was anæmic. According to Dr. Napier's advice I started with 0.1 gram of the compound; after three injections the bruit disappeared and the piles were cured when the injections were completed.

In case 3 the feet got swollen after four injections. On repeated examination of the urine no albumen was detected; the swelling passed off itself without any treatment.

The only difficulty about the drug is that it is not always available in the market and the prices are a little too high for poor patients. If the prices are so reduced that it can be used by the poor (kala-azar being more commonly observed amongst the poor than amongst the rich) the combat with kala-azar will be made easier.

In conclusion I offer my hearty thanks to Dr. L. E. Napier who kindly encouraged me to try the compound and also gave advice whenever necessary.

A Mirror of Hospital Practice.

A CASE OF INTERNAL STRANGULATION BY THE SPERMATIC CORD.

By M. N. S. CHETTI, L.M. & S.,
Civil Surgeon, Sagaing.

A YOUNG Burman lad, 17 years of age, was admitted on 28th October, 1924, with a history of pain and distension of the abdomen of 2 day's duration. He was brought from a village in a cart, but walked into the hospital with body bent suggesting some abdominal trouble.

On examination the abdomen was found to be distended like a drum and tender all over. The pulse rate was 90 per minute, the respiration 30 and the temperature was normal. He had just commenced to vomit. Although nothing pointed to any trouble in the scrotum, this was examined. The skin of the scrotum was loose. The testicle with its sac was felt to be tense, but no tenderness was elicited. There was no evidence of bulging of the inguinal canal nor enlargement of the external ring. The usual signs of an ordinary inguinal strangulated hernia were absent. There was absolutely no pain over the ring.

The patient was given an enema with no result. He was immediately prepared for an operation and was put on the table. There was some hesitation about the selection of the site of incision and finally it was decided to open the inguinal canal to find out if there was any cause of obstruction. The incision was made over the external ring both above and below. A small sac was exposed and incised and a small quantity of brownish-red fluid was emptied out. The testicular substance was dark-purple in colour and was found to be tightly gripped at the external ring above the globus major. An attempt was made to pull the testicle downward without success. The external ring was gently and gradually incised; when it was sufficiently cut the testicle went into the abdomen with a snap. There was

nothing else in the sac on the inguinal canal. An attempt was made to search for the lost testicle inside the abdomen through the internal ring, but it failed. The usual operation for hernia was performed and the patient put back to bed.

Three or four hours after the operation the patient passed a large watery stool containing the enema and faecal matter; he passed a good deal of wind and the abdomen gradually began to get flat and soft. The patient recovered without any untoward result, and was discharged on 25th November, 1924, with instructions to come back and show himself after three months, or earlier if there was any further trouble. It is nearly four months since he left the hospital and it is naturally inferred from his non-appearance that he has been doing well up to this time.

The object of publishing this case is to emphasise the importance of careful examination of the scrotum in all cases of acute intestinal obstruction.

Though in this particular case there was no strangulation, either of omentum or of intestines in the external ring, yet the cause of internal obstruction was there.

Further, it is also intended that readers of this article will kindly communicate their views to the writer of this article, directly or through the medium of this journal, regarding the causation and the proper procedure of operating on such cases which are indeed rare.

GANGRENE OF THE TESTES AFTER TORSION OF THE SPERMATIC CORD.

By M. N. S. CHETTI, L.M. & S.,
Civil Surgeon, Sagaing.

A BURMAN male aged 47 years was brought to the hospital on 1st April, 1925, with a history of enlargement of the right testicle with swelling about 9 days ago without any cause.

On examination the tumour was found to be somewhat about the shape and size of a medium-sized mango extending above the external ring. The upper one-third was soft and fluctuating covered by healthy skin—the lower two-thirds hard with œdema of the skin over it. At first sight it looked like a strangulated hernia, but the history and signs were against it. It was diagnosed as a case of hæmatoma of some unknown traumatic origin. The left half of the scrotum and the left testicle were absent.

On making the usual incision for radical cure of a hydrocele, over the inflamed and œdematous area, there was some unusual exudation of blood between the scrotal tissues and the tunica vaginalis. The latter was of a bluish dark colour and very tense. On incising the tunica vaginalis there was some dark-coloured blood with some clots. On clearing up the sac the testicle was found to be bluish-green in colour and quite soft and looked as if it were gangrenous. Now the difficulty arose as to whether the testicle should be removed or not. Not knowing definitely the cause of gangrene the incision was enlarged upwards as far as the external ring, the point at which the

greatest pain was felt by the patient on first examination; it was found that the cord had twisted completely once round on itself just below the external ring, thus causing strangulation of the testis. Although the left testicle was absent from the scrotum it was imperative that the strangulated testicle should be removed. It was accordingly removed above the site of torsion.

So far as I am aware I have never seen a case of torsion of cord causing gangrene of the testicle though it is mentioned in text books. It is very rare indeed.

In this case I think the torsion was due to the free play of the testicle in all directions for want of the lateral support which it has when a second testis is present.

It is brought to the notice of the profession that such torsion of the cord may occur and it is worth while remembering this case which might help us in making a diagnosis of scrotal tumours resembling hematoma of the testicle without any traumatic history and that torsion of the cord may occur in people who have only one testicle completely descended into the scrotum.

A CASE OF PEDUNCULATED PAPILLOMA OF THE TONGUE.

By H. J. H. SPREADBURY, M.B., M.R.C.S.,
Monacherra, Cachar.

A. R., male, aged about 50 years, came to see me on 9th March, 1925. He complained of a growth on his tongue, first noticed between two and three months ago. This had rapidly increased in size, and was now causing him great difficulty in eating his food. The growth also showed a tendency to fall backwards during his sleep, and on several occasions he had awoken choking. About a month ago he gave a history of swelling pain and tenderness in the submaxillary region; this had subsided.

On examination I found a large pedunculated tumour, about one and a half inches long, one inch broad and half an inch thick, lying on the dorsum of the tongue, and attached to it by a pedicle half an inch in diameter immediately anterior to the circumvallate papillae, in the mid line. The tumour was soft, purplish-grey in colour and lobulated at its distal border. There were no signs of ulceration, but the tongue was coated with a thick yellowish-white fur and the breath was extremely offensive. No enlargement of the cervical glands was noted.

He could not be persuaded to remain in hospital to have the tumour excised. A simple ligature of stout thread was therefore applied at the base of the pedicle, he was given an antiseptic mouth wash and allowed to return to his home. He was warned against sleeping on his back until separation had occurred.

The patient was seen again a fortnight later; he said that he had swallowed the tumour with his food on the fifth day after ligation. On examination his tongue was clean, and there was a slightly depressed smooth scar about half an inch

in diameter immediately anterior to the circumvallate papillae. The scar showed no signs of induration and no cervical glandular enlargement was noted.

The interest of this case lies in the fact that papillomata of the tongue are rare and, when they do occur, are usually sessile; also that malignant changes are liable to occur in them.

A SWALLOWED CORK-SCREW.

By H. M. HANDE, L.M.P.,

Government Lawley Road Dispensary, Coimbatore.

A FEMALE child, aged 3 years and 5 months, in the Agricultural College Estate, swallowed at 7-30 p.m. on 14th May, 1925, a metal cork-screw of the kind usually supplied with the Panopeptone bottle; it measured a little over 1 in. long and had three coils, at the head of which there was a tiny horse-shoe shaped handle. The circular handle which is usually attached to this type of cork-screw had been removed, otherwise the child could not have swallowed the thing. The point of the screw is pretty sharp. The child was brought to me at 8-15 p.m., within less than an hour after the incident—when after a little hesitation whether to give an emetic or a purgative, the latter was decided upon, as I thought an emetic might be unsafe considering the nature of the foreign body. One ounce of castor oil was administered statim and the child was advised to be fed with bulky food such as rice and bread. On 15th May, 1925, another ounce of castor oil was given and the child passed 6 semi-solid and watery motions. On 16th May, 1925, there was no motion at all. On 17th May, 1925, at about 1 p.m. the child had a solid motion in which the cork-screw was found imbedded—nearly 65 hours after the accident.

A CASE OF UNDETECTED GUNSHOT WOUND.

By Dr. PITAMBER PANT,
Civil Surgeon, Bijnor, U. P.

CONSTABLE, Mohammad Ayub, aged 25, was admitted into the Police Hospital, Bijnor on the 16th April, 1925, for arthritis of the left ankle joint. He gave the following history:—About ten months ago he was on special duty and whilst pursuing a dacoit during the night he struck against a stone and tripped. The next morning he noticed that his left ankle was slightly swollen and painful. He applied some tincture of iodine and the swelling subsided within 2 or 3 days but he still felt sore about his ankle. However, he did not mind this and continued to do his work. Later on he went on a month's leave and on return from leave resumed his duty. He did his ordinary work without any trouble, but a week before his admission into hospital he was put on fatigue duty and this set up such a severe pain in his left foot that he had to seek admission into hospital.

On admission there was just a suspicion of the left ankle being swollen. The patient was treated

with counter-irritants, hot fomentations and massage, but to no good.

Any swelling that there was had disappeared after over a month's stay in hospital but the man was still limping and could not use his foot although there was no displacement or swelling. It was then suspected that there might be a fracture of one of the bones of the tarsometatarsal joint. He was, therefore, sent for an x-ray examination to the Dehra Dun Institute when it was discovered that there was a shot lying in front of the left external malleolus (vide skiagram).

This case is interesting inasmuch as the patient himself had no idea that he had received a gunshot wound.

On being questioned again he admitted that shots had been exchanged on the night when he had tripped and that a sub-inspector had been severely hurt with gunshot wounds at the same time; he hadn't any recollection as to whether there was any hæmorrhage from his ankle at the time. An examination, however, showed that there was a minute linear scar on the inner side of his left ankle.

The shot was removed and the patient made an uneventful recovery.

A CASE OF MALIGNANT PUSTULE.

By GANAPATI PANJA, M.B.,

Assistant Professor of Bacteriology, Calcutta School of Tropical Medicine and Hygiene.

B. A., Mahomedan male, aged about 25, apparently in good health, came to the out-patient

department of the Calcutta School of Tropical Medicine with a localised swelling on the front of his left upper arm, near the axilla. The swelling was of twelve days' duration and started spontaneously with a vesicle. It was oval, about $1\frac{1}{2}$ inch long and consisted of several vesicles merged into one another with a depressed central small scab from which strings of swollen lymphatics were seen radiating towards the periphery. The patient had no fever, no enlarged cervical and axillary glands, and pain was slight; in fact he did not seem to take much notice of his disease.

A culture was taken on blood agar and the next day colonies were seen with spiky outlines. They were stained and identified as *B. anthracis*. Further tests were made to prove their identity.

About two days later the patient was seen again and questioned about his occupation. He said that he had been working as a hide bearer

for about two years and had not heard of any of his fellow-workers suffering from a similar disease.

The case is interesting from the following points of view:—

- (1) The disease is rarely seen.
- (2) There were no toxic symptoms.
- (3) The central black scab was absent even after 12 days' duration.
- (4) The site of the lesion was near the axilla although the commonest site is the back.

The photo illustrates the case.

Indian Medical Gazette.

SEPTEMBER.

THE TYPHUS-LIKE FEVERS.

AN important addition to the literature of this widespread and imperfectly understood disease group is the paper on "So-called Pseudo-Typhus," by Dr. Andrew Balfour, in the *Kenya Medical Journal* of March 1925.

In this paper there are numerous references to records of typhus-like fever in various parts of the world. Most of these have already been referred to by me in various notes in the *Indian Medical Gazette*, but Dr. Balfour's article supplies further information which is of importance to those who are interested in this intriguing group of diseases.

Dr. Balfour gives several references to a condition known to the French as "fièvre boutonneuse," which has been described, in and round Tunis, by Connor and Bruch. This is probably the fever which has been referred to in the English literature as the "spotted fever of Tunis"; it obviously belongs clinically to the typhus fever group, and at one time I thought it likely that the disease might belong to the tick-typhus group,* but as nothing had been heard of the disease for several years and as louse-typhus has been a good deal in evidence in Tunis, I decided that it would hardly be justifiable to include the disease in one of the groups of non-louse-borne typhus group fevers.

Fièvre boutonneuse is not referred to in the 1924 edition of Le Dantec's excellent book on exotic diseases, this fact combined with the absence of epidemiological data in connection with the disease strengthened my impression that the disease might be louse-borne.

Some of the points quoted by Dr. Balfour, such as the usual involvement of palms and soles by the rash, the earlier appearance of the rash and the frequent affection of European women are rather opposed to the view that it is louse-borne typhus. Possibly we may hear more about the disease now that the possibility of ticks and mites being vectors of such diseases is more generally recognised.

Dr. Balfour gives some information of 42 cases of a similar typhus-like fever in Europeans, reported by Dr. Gilks in his *Annual Medical Reports* for 1920 and 1921.

These cases occurred in Kenya, in Europeans, and lice infestation appeared to be very improbable; there was only one fatal case. The Weil-Felix reaction is said to have favoured the idea that the disease is typhus. Evidence has now been brought forward of the existence in many parts of the world of typhus-like diseases which are probably not conveyed by lice; there is no

evidence of person-to-person infectivity and the diseases differ clinically from louse-borne typhus. In some places like Japan and Sumatra the disease has been proved to be conveyed from an animal reservoir to man by mites, in the Rocky Mountain region it has been proved to be conveyed from an animal reservoir to man by ticks. In several cases in India the disease followed definitely after tick bite and the existence of a tick-borne typhus-like fever is almost certain. In other places such as the Transvaal, Nigeria, Kenya, Tunis, Queensland, French Indo-China and recently in the Malay States, cases have been reported which are not likely to be louse-borne but which are typhus-like in their clinical manifestations. The striking feature of all these cases is their association with the conditions of the wilds, and hence they are probably conveyed from an animal reservoir by ticks, mites or other arthropods. Some of the cases give a positive Weil-Felix, others a negative, and others have not been tested.

The tick-borne disease of the Rocky Mountains has been proved to have a pathology essentially similar to that of louse-borne typhus, and some recent workers believe that the mite-borne disease is of the same group. Clinically there are good reasons for a provisional grouping of the louse, tick and mite-borne diseases as "typhus-like diseases" or more simply as "louse-typhus," "tick-typhus," "mite-typhus" and "typhus of unknown vector," as suggested by me.

It must be understood that only the louse-typhus and tick-typhus have been proved to have an essentially similar pathology so that the only justification for including the other typhus-like fevers in the same group is practical convenience and expediency. The classification may prove later on to be unscientific but it has the great advantage of calling the attention of workers to the clinical features and the possible vectors of the diseases. As a rule, the tick-typhus fevers show a negative Weil-Felix reaction. There is a rash which often invades the face, palms and soles; and except in the Rocky Mountains the mortality is low. Mite-typhus usually shows a local papule or sore at the spot where the mite has bitten, the local lymph glands are enlarged; the mortality, except in Japan is usually low.

There are many interesting possibilities in connection with the widely distributed typhus-like fevers; for instance, there is just a possibility that the ticks of the jungle originally became infected from human typhus and so started the disease among the rodents of the wilds. Opposed to this are the slight differences in the clinical manifestations and the usually negative Weil-Felix reaction in the tick-borne disease. The mite-borne disease of Japan does not protect monkeys against louse-typhus, and the clinical manifestations of the mite-borne disease are rather sharply different from those of louse-typhus so that the virus of the two diseases is not likely to be derived from the same ancestor.

* *Indian Medical Gazette*, Jan., 1917.

To the records must be added "Schara boil"; of which 72 cases were described from West Russia, in the autumn of 1917, by Rissom (*Arch. f. Schiffs and Tropenhygiene*, 1918, p. 273). This closely resembles the Japanese river fever in the presence of a local sore with local gland enlargement and a characteristic skin rash appearing on the 8th to the 12th day.

Mites were not discovered on the bodies of the patients but there was reason to suspect them strongly, as mites were found in numbers on the ears of the field mice of the locality.

J. W. D. MEGAW.

SPECIAL ARTICLE.

THE RAMBLINGS OF A PUBLIC HEALTH OFFICER.

By A. J. H. RUSSELL, M.A., M.D., Ch.B., D.P.H., D.T.M.,
MAJOR, I.M.S.,

Director of Public Health, Madras.

(A paper read before the South Indian Branch of the British Medical Association in March 1925).

WHEN I agreed to speak to this association on some of the experiences of my recent leave, I did not realise how impossible it was to give any adequate idea of my ramblings until I had set myself down to the task. I wish, therefore, to state at the commencement, that if my remarks appear to be somewhat disjointed, as I am afraid they will be, this is largely due to the fact that I have been compelled to leave out so many points of interest.

As you are aware, Colonel Cunningham and myself were deputed to attend the Far Eastern Association of Tropical Medicine congress held at Singapore in September 1923. After leaving India the first port of call was Penang, which is probably one of the most beautiful islands in the world. As in most of the Federated Malay States, however, malaria is common there and we were at once struck with the very ingenious methods adopted to prevent mosquito breeding in the town.

R. L. Stevenson in one of his essays tells how an eager Japanese student welcomed mosquitoes because their bites kept him awake over his books. The method of repelling slumber does not find favour in the towns of Singapore and Penang, nor are the medical men of the Dutch East Indies any less enthusiastic in their efforts at extermination of the insects.

"In Malaya Peninsula indeed where neither cholera nor plague causes any serious mortality, malaria occupies an even more important place in the eyes of the sanitarian than it does in India," and as there is no "financial stringency," the colonial Government is not afraid to spend money and the campaigns conducted against mosquitoes are admirable. This was especially the case in Singapore itself where, in July 1911 a terrible wave of malaria raised the death rate to 85.83 per mille. Later figures show the progress made.

1903-12	44.11
1913-22	33.73

a reduction of 10.38 per mille or a saving of 32,214 lives.

During the conference in Singapore, many very interesting papers were read, but perhaps the best from a scientific research point of view were those presented by the delegates from the Dutch East Indies.

Dr. Walch's paper on "pseudo typhus" and Dr. Van de Velde's on "dengue-like fevers caused by spirochaetes" were models of their kind, and the paper by Dr. W. B. Doorenbos on the Sumatra system of sanitation and health control on the Holland-American Plantations demonstrated the economic value of a carefully

planned health organisation, and made one wonder when it would be possible to have anything so complete in India.

It was the enthusiasm of the Dutch East Indies medical men, particularly Dr. Vogel, Dr. Lonkhuzen and Dr. Walch, which revived the Far Eastern Association in 1921 after an interval of eight years, and it was at the instance of the conference held in that year in Java that the League of Nations health section decided to despatch to the Far East a medical commission with special experience of international public health agreements and of the epidemic diseases of warm climates. The recent conference held at Singapore to discuss the formation of an Epidemic Diseases Bureau for the Far East is the sequel to that commission. Such a bureau will be of immense value in recording and distributing information regarding epidemic diseases in Far Eastern countries.

The conference had long and serious discussions on the question of an international organisation for disease control, with special reference to beri beri, but none of the Far Eastern countries desires to take the initiative lest the industry of its own exporters and millers is disturbed, and the plantation managers will not begin to use brown rice in case they have difficulty with their labour. The result is that progress becomes impossible.

In Singapore a new General Hospital and a new Medical College were under construction, large sums of money having been allocated by Government for this purpose. But as Dr. Hoops said in his presidential address, "overcrowding and bad feeding are the two primary factors in the causation of disease in the cities of the East" and certainly in Singapore dreadful conditions of overcrowding, lack of ventilation and resultant tuberculosis exist in the Chinese parts of the city. Sleeping accommodation is provided in cubicles built like ship cabins with two to three in each cubicle, sometimes 60-80 persons being housed in a couple of rooms.

Better housing for the working classes has been a political cry for many years, but alike in the east and the west, still remains an unsolved problem. In many cities indeed, the slums are a disgrace to civilization. Recent investigations show, moreover that, particularly among Eastern peoples, the great bulk of the population is badly fed and improperly nourished. So long as such conditions prevail, are not the nations of the world wasting money in the building and maintenance of pre-natal clinics, child welfare centres, maternity hospitals, training centres for midwives, post-natal clinics, sanatoria for tuberculosis, venereal clinics and school and dental clinics? Surely these activities merely touch the very outermost fringe of the problems associated with the primary evils responsible for the production of disease. The question arises, what permanent advantage does a child gain at a baby welcome or child welfare centre when its mother is compelled by poverty and ignorance to feed it on rice and kunjees and the home is a dark unventilated hovel, incapable of improvement.

It is quite impossible to make more than passing reference to Hong Kong and Shanghai. The former port, the largest in the world, has grown in population at an enormous rate during the last 10-20 years, and the restricted area available on the rocky island for streets and bazaars is dreadfully overcrowded. Still Hong Kong has a fine University at which large numbers of Chinese students graduate in medicine and arts. The International Health Board takes an active interest in this University, and it so happened that Dr. Shellshear, professor of anatomy, who was the only member of the staff I met, was an old Rockefeller scholar.

In Shanghai, I had my first insight into the Chinese method of collecting and conserving night-soil, a great proportion of the night-soil of the town being carried in barges many miles inland for purposes of cultivation. When the large tanks were filled and covered over and the decks swabbed down, the barges did not look at all unseemly and the whole process was carried out in as sanitary a fashion as possible, although it was obvious

that there was nothing to prevent the spread of hook-worm.

Shanghai is a city made up of a group of foreign concession areas plus a Chinese town. The Health Officer of Shanghai, Dr. Davis, who kindly placed his Chief Sanitary Inspector and a car at my disposal, supervises the public health work in the area which formerly comprised the British concession, and the enormous Chinese population of three-quarters of a million living immediately outside have nothing done for them at all. In the circumstances it is surprising that epidemics do not occur more frequently.

In Peking we spent a fascinating fortnight. The bazars are intensely congested and the streets are in much the same condition as those of Madras. When the north wind blows and raises the grey dust, which lies inches thick everywhere, it is not wise to leave the refuge of one's hotel.

I had opportunities of visiting one or two of the better class Chinese houses and found them laid out much on the same plan as Indian houses—with the rooms opening out on a central square. They must have been hot in summer and as I know, were cold in winter, as the paper windows did not give much protection from the icy November winds blowing from the snowy Siberian steppes.

The Rockefeller Foundation have now completed the reconstruction of the Peking Union Medical College and Hospital which were formerly managed by a body of medical missionaries. The whole buildings, modelled on old Chinese architectural designs, have been built on a lavish scale, and the courtyards in marble, and the beautifully carved roofs with their glazed green tiles, gave an impression of magnificence which at first made one full of envy. The total cost amounted to eight million dollars, and I should imagine that the hospital does not have its equal in the world, for modern equipment and fittings. Not only are wards and laboratories fitted throughout with all manner of electrical contrivances, but the kitchens and laundry are entirely run by electricity. The professorial staff, which included the usual number of Scotsmen, were all carrying out research work of one kind or another. The professors of hygiene and of pathology, for instance, during the vacation months, did a great deal of field work, away in the interior, in connection with different epidemic or endemic diseases such as hookworm and kala-azar. This last disease has a very high incidence round Peking itself and has also been reported from other large areas of China. The whole of the college staff gave one an impression of intense keenness and enthusiasm; but it must be very difficult for a Chinese student, trained in such a gorgeously equipped school, to go into the interior and with nothing (perhaps not even pay for months, not to speak of prospects) try to keep up what he has learned and practice the methods which are so easy to conduct in such an up-to-date hospital. The students were few in number, but I gathered that this was not a cause for regret meantime. The college laboratories are small, much too small in my opinion, and I think it is legitimate criticism to say that a great deal of space and money has been wasted in the development of external architectural features which might have been spent much more advantageously. I believe I have the support of Mr. J. Rockefeller, Jr. in this expression of opinion.

Before leaving China, I wish to touch upon a subject which applies with almost equal force to India, that is, the question of the growth of the population. In China, sanitation does not exist, and in spite of the constant destruction of human life from epidemic diseases, and in spite of an enormous infantile mortality, the country is so over-populated that the great majority of the people is continuously and hopelessly occupied in striving to grow, or collect, food sufficient to keep body and soul together. Here is an estimated population of over 600 millions, so engrossed in the mere scramble for the bare necessities of living, that national progress, mental,

moral and spiritual is impossible. And what of India in the same connection? Mathematical analysis of the statistics of its population during the six censuses taken from 1871-1921 show that *under present conditions*, the population cannot increase much further without causing a serious shortage of food, and perhaps it is not realised that already for some years past Madras Presidency has been compelled to import rice in order to feed the present population. It is almost certain that the food question has been at the bottom of all wars between nations. If the Indian population does jump above the asymptotic line, the sequel must be an epidemic or a famine, or it may be a war or a revolution sufficiently terrible to bring the population below the asymptote once more.

Passing over an 18-days voyage across the Pacific, by means of a magic carpet or similar contrivance, we find that in the United States the same questions regarding population are being asked, and the biologist and eugenicist have questioned the ultimate value and wisdom of some of the work which is being done by the public health worker. The new American immigration laws have been unanimously passed because of the same doubt. The constant influx of low grade and highly prolific immigrants from Southern and Eastern Europe, which had passed unnoticed for many years before the war, attracted immediate attention when the United States took stock of her man power in 1917. It was found that the descendants of these Mediterranean races, the lowest classes in America, least fitted for the responsibilities of parenthood and least apt to transmit desirable qualities to offspring, were increasing rapidly, whilst the marked decline in the birth rate of the upper classes continued. It has been calculated that the United States can support a population of nearly 200 millions. The 1921 census showed the population to be 110 millions, so that it is not difficult to calculate the date on which the country will reach saturation point.

Carry the argument a little further and suppose the world population also to have grown in the same proportion as it has been growing during the last four or five decades, and we reach the stage when all the peoples of the earth will be compelled to descend to the scale of life which is now necessary in China, a constant scramble for food. The question arises—can we do anything to prevent such a catastrophe? Many will "pass by on the other side," in the conviction that so long as the food question does not press too strongly in their days, the problem can be ignored. But since the days of Pasteur, preventive medicine has lowered the general rate, diminished the incidence as well as the death rate of infectious diseases, and the latest 'stunt' is the saving of numbers of children under 5 years of age, who a few years would certainly have been doomed to die. Public health activities have therefore added years to the general expectancy of life as well as to the productive and procreative period of life, but it is not so certain that these activities have been wholly for the benefit of the human race. Indeed, as a eugenicist, I am firmly of opinion that in many instances, what I have done as a public health officer is wrong. The humanitarian view which always does and always will influence public health work has been allowed to guide our actions far too long. The biological view must and does condemn the breeding of mental defectives and degenerates, but nowhere is there any system that is to any degree adequate for preventing those unfortunates from procreating their kind. If people would only think of the enormous sums of money and the amount of food wasted in keeping those unproductive classes alive, and the many useful directions on which that money could have otherwise been spent for the nations' benefit, the humanitarian side of our nature would soon show a falling off and we would see to it that methods were sanctioned by law which would effectively sterilise those who by every canon are unfitted for parenthood. I have however rambled on this subject sufficiently long, but it is certain that from the sociological, the eugenic and the public health points of view, these questions require more study than they have hitherto received.

A period of strenuous travelling gave me a general insight into public health administration in a number of municipal and rural areas in the United States, and it may be said at once that from the broad administrative aspect, we in Britain and British-India have nothing to learn from the Americans. In most of the large cities, Chicago being no exception, part-time health officers were employed. Well, even in Chicago I am of opinion that a part-time health officer is a whole-time joke, and I had no occasion to change that opinion when I made enquiries as to the work done. All state and city public health appointments, like other departmental appointments, from the health officer down to the sanitary inspector and the head clerk in the office are subject to the political party in power, and I was amazed to find that in Baltimore for instance, the health officer had been out and into his appointment five or six times in his 30 years' service, according to whether the Democrats or Republicans gained a majority. I must hasten to add, however, that this custom is disappearing to a certain extent, but try to imagine this method carried out in India! Verily, the fruits of office, with a vengeance! Health propaganda work in America is generally very cleverly done and money is freely spent on such campaigns; but in some places it seemed that the method adopted was to frighten the people to death. One bulletin describing the horrors of venereal diseases may be described "as the most ungentle thing in the shape of propaganda I have ever seen."

Americans apply accepted hygienic principles to their ordinary life much more than other European races. Everywhere one saw cupless spouting fountains of drinking water, paper cups or containers, paper towels, etc., etc.; but spitting in the streets is ubiquitous and "spittoons" or "cuspidors" are to be met with everywhere in trains, restaurants, etc. Not always does the shot find the bull's-eye, so that conditions are at times quite revolting. If anything the houses are overheated, but American houses are generally much more comfortable than those at home.

Town milk supplies are mostly graded and certified and are dealt with in ideal fashion, but in rural areas and in the smaller towns conditions are no better than those in other countries.

'Prohibition' is not going to be cancelled, as the great mass of public opinion is in favour of it. It is the fashion at present for certain sections of the community to try to defeat the law, and large quantities of wood alcohol, 'moonshine' spirit and similar dope is consumed, but with the next ten years a new generation will have grown up, to whom alcohol is unknown, and prohibition will be an accomplished fact, to the eternal credit of those who believed that alcohol was a stumbling block to the nation's progress and who successfully introduced the prohibitory legislative measure now known as the 18th amendment to the United States constitution.

But my rambling must not further postpone my arrival at Johns Hopkins University, where I spent a very profitable and very strenuous four months studying statistics and statistical methods under the guidance of Prof. Raymond Pearl and his associate Prof. Dr. Reed. It was a little difficult to plunge straight into the differential and integral calculus after an interval of nearly 25 years, but being the only British representative in the cosmopolitan community of 43 post-graduates in the School of Biometrics I felt compelled to keep my end up, and every possible facility was placed at our disposal. Before leaving Baltimore I completed the part of the statistical research on cholera I had in mind when I arranged to go there; but that will be the subject of a number of papers to be published shortly. Johns Hopkins is, of course, the medical school of America, and the whole staff was so imbued with the scientific spirit that it was a pure delight to live and work among them. Several members of the professorial staff were Canadians among whom I would mention Dr. MacCallum, the professor of pathology. He took me over his new pathology block,—a huge seven-storey building, which had just been completed at a cost of 2,000,000 dollars.

At the time of my visit he had no less than 25 post-graduates doing research work under his supervision, and as each of these men did a number of hours tutorial teaching a week, for the 90 medical students on the roll, there were 28 teachers, including Prof. MacCallum himself and 2 university assistants. Dr. MacCallum, the professor of physiology, of dietetic fame, on several occasions invited all those interested to inspect his laboratories and rat houses, where wonderfully controlled feeding experiments were being carried on, and time alone forbids my mentioning any others except Dr. Welch, the Principal of the School of Hygiene, whose name will always be known in connection with the *B. welchii*, or *B. aerogenes capsulatus*, which is frequently found in cases of septicaemia and gangrene. My experience in the School of Biometrics confirmed the opinion I had formed, long before I went to America, regarding the official statistics and the statistical forms in use in the medical and public health department in this country, viz., that they are as useless as they could well be. Not that the information that can be obtained from them is useless, far from that; but the present arrangement and tabulation methods are such that information can only be obtained from them with the greatest difficulty. The public health department has managed to convince the Local Government of the desirability of re-arranging and re-classifying and simplifying the forms in use, so that we have already cut out quite a large number of items which had gradually been added but the reasons for which had been long ago lost in the mists of antiquity. I commend the question of revision of statistical forms to the Surgeon-General and the superintendents of hospitals in this Presidency, that is to say, if they desire the statistical information contained therein to be readily available.

The School of Hygiene in Baltimore of which the Biometrics School formed a part, was perhaps the most actively alive part of the whole university. The authorities had recognised that the teaching of hygiene in all its manifold branches could only be done properly by having a large teaching staff, and the Johns Hopkins school had no less than ten professors, including Dr. Welch, the Principal. The subjects were divided somewhat as follows:—

- 1 Principal (lecturer on special subjects).
- 1 Professor of Public Health Administration.
- 1 Professor of Bacteriology.
- 1 Professor of Immunology.
- 1 Professor of Epidemiology.
- 1 Professor of Chemistry.
- 2 Professors of Vital Statistics.
- 1 Professor of Sanitary Law.
- 1 Professor of Sanitary Engineering.
- 1 Professor of Parasitology, Entomology and Helminthology.

During the whole session a weekly programme of special lectures was arranged, these being given by distinguished scientists engaged in different branches of public health. Set lectures by the professorial staff were only given when absolutely essential, and most of the students' time was spent in the laboratories. The course in epidemiology, for example, was eminently practical, each student being given weekly a set problem in connection with a specific epidemic,—data from actual outbreaks of disease being supplied, not 'hypothetical happenings,'—which he had to work out for himself and submit for criticism. During the two terms I attended the School of Biometrics, the lectures number only six to eight all told, and we spent eight hours a day in the laboratory, working problems with the aid of calculating machines which on first acquaintance seemed almost uncanny in their exactness, but later on became essential even for adding up a bridge score. The permanent staff of each department spent a great part of their time in research work. For instance Dr. Raymond Pearl was busily engaged in calculating the hereditary effects of alcohol and other similar substances on generations of flies while the seven or eight research scholars were all carrying out different pieces of statistical health

work under his guidance. The constant mental stimulus experienced in an atmosphere of this kind was remarkable, and in my opinion was the most valuable return I had for the expenditure incurred. I have described in some detail the School of Hygiene as I saw it in Johns Hopkins, as I wish in conclusion to plead for an improvement of the teaching of hygiene in Madras. It is now some ten years since the university asked me to revise the regulations for the B.S.Sc. degree; but the time is now ripe for another drastic revision and for more drastic proposals regarding the necessary teaching staff, if this Presidency is to maintain its position as the pioneer in public health work in India. Now that a real live public health department has come into existence with a trained staff in each district, not only must all would-be candidates receive thorough training, which I maintain it is impossible for them to get at present; but there must be provision for post-graduate and refresher courses at which health officers may add to their equipment in their fight against disease. This implies the formation of a School of Hygiene or an Institute of Public Health, call it what you will; but, whatever the name, the institution must have a suitable number of teachers with special knowledge of the subjects they profess. The term "principles of hygiene" means nowadays not only the general practice of preventive medicine, general sanitation and administration but includes hygiene of childbirth and infancy, school hygiene, mental hygiene, industrial hygiene, tuberculosis, venereal diseases, control of food supply, sanitary construction and planning, selection and supervision of water supplies and port and marine sanitation. While it will probably be impossible, for many years to come, to emulate the staff of the Johns Hopkins School of Hygiene, nevertheless I would suggest that in Madras the minimum requirements now are:—

- (1) a professor of hygiene (including public health administration and sanitary law,
- (2) a lecturer in chemistry,
- (3) a lecturer in bacteriology and immunology including parasitology and possibly entomology and helminthology,
- (4) a lecturer on vital statistics and epidemiology;
- (5) a lecturer on sanitary engineering,
- (6) assistants to (1), (2) and (3) and possibly (5).

Practical courses on each of these subjects would of course be given. This staff would probably also be able to give the necessary courses of instruction to sanitary inspectors but the M.B. class in hygiene, at least, ought to be carried out by a separate teacher attached to the medical college staff.

These proposals may seem extravagant to some of my audience, but you will perhaps realise how my ramblings carry me when I add that, in my opinion, they are the bare minimum now and will require amplification in years to come; for I envisage a time, not so far distant, when the Government Medical Department will be totally abolished, and when a State Public Health Department will have extensive ramifications over every district in the Presidency and will be safely entrusted with the protection of the population from disease, a function than which none can be higher or more soul-inspiring.

Current Topics.

Encephalitis Lethargica.

By C. M. HINDS HOWELL, M.D., F.R.C.P.
Brit. Med. J., March 7, 1925, p. 437.

In the spring of 1918 a series of cases appeared in England which presented certain novel features. Since that date we have had the disease constantly with us. In January 1919, notification was made compulsory by the Local Government Board. The number of cases notified since then has been: 541 in 1919, 890 in 1920, 1,470 in 1921, 454 in 1922 and 1,123 in 1923.

The incidence of the disease is highest in the winter months January, February and March. The age incidence is fairly evenly distributed. The disease may occur in babies or septuagenarians. The disease is contagious to only a very slight degree; in this respect the disease resembles poliomyelitis and meningococcal meningitis. But cases are on record of direct spread by contagion, though their numbers are few.

In 1919 and 1920 Strauss, Hirschfeld, and Loewe, succeeded in reproducing the disease in the monkey (*Macacus rhesus*), and in rabbits, by using emulsion of brain from cases of encephalitis lethargica. They were also successful with washings from the nasopharynx of living patients. They isolated a virus from this material which proved to be a filter-passer, and also to be capable of preservation in glycerin. In these respects it closely resembles the virus of poliomyelitis.

It is probable that in both these diseases as also in meningococcal meningitis, the infecting agent gains access to the central nervous system through the nasal mucosa, and that in all of them "carriers" exist.

A review of past influenza epidemics reveals the fact that cases presenting a clinical picture very similar to that of encephalitis lethargica occurred in these times. It seems clearly established that epidemiologically there is a close connection between influenza and a group of diseases affecting the nervous system, of which encephalitis lethargica, cerebro-spinal fever, and poliomyelitis are members.

The onset of the disease may be acute or very insidious. The oculo-lethargic group of cases may show diplopia of doubtful origin and little else. The initial period in these insidious cases may be prolonged, constituting what may be regarded as a prodromal period in which the chief symptoms are lassitude, somnolence, slight headache, depression, and irritability. When the disease enters on a more active stage, and in cases of sudden and acute onset, fever is always present. Its duration may be matter of hours, or it may be present for weeks, but the febrile period is as a rule short. In two cases the patient was febrile for a period of eight weeks. One of these patients recovered. Although commonly of low grade, high degrees of fever, sometimes even hyperpyrexia, may occur. Abdominal pain associated sometimes with vomiting, may occur. Polypnoea with periods of apnoea has been observed on several occasions. Drowsiness is one of the striking features of the disease, both in its active stage and as a sequel. It is often one of the earliest symptoms. The condition of drowsiness frequently advances to one of seemingly profound lethargy; it is remarkable how a patient in such a condition can be roused to answer a question intelligently, but at once relapses again. The lethargic periods often show remarkable remissions.

With this profound lethargy the patient may frequently suffer from insomnia. This may simply be inability to sleep at night, but is sometimes accompanied by nocturnal excitement. Among symptoms due to lesions in the nervous system ocular phenomena take first place. Any or all of the oculomotor nerves may be involved, the paralysis usually being of the nuclear type with conjugate movements affected. Ptosis is extremely common, and helps to add to the appearance of somnolence which is so characteristic. The pupils show a variety of changes, small, dilated, unequal, the Argyll-Robertson type, and failure to react to light or accommodation.

Other cranial nerves may be affected, the commonest being the seventh. The patient may quite early exhibit the Parkinson facies, with characteristic attitude of the arms and hands, rigidity, and, less commonly, tremor. Chorea movements, choreo-athetoid movements myoclonus, and muscular spasm may occur. Epileptic attacks may occur as an initial symptom, during the course of the disease, or as an after-effect; they are not a common symptom in the disease.

One of the most striking sequels is paralysis agitans. Parkinson symptoms may appear early, they may entirely disappear, or pass into a chronic and persisting residual condition. On the other hand cases in which

the patient appears to have made a good recovery may begin many months later to develop the characteristic symptoms of paralysis agitans.

Residual ocular paralysis is common—the degree very variable. Mental changes are also unfortunately very common. The bright child becomes dull, the “easy” child “difficult.” Depression, sometimes amounting to melancholia, is not uncommon. Impulsive tendencies are noticeable in a few cases; one patient always felt the strongest impulse to get in front of express trains, or if water were rushing under a bridge to jump into it, though she had no wish to commit suicide. Disorders of sleep may persist long after the acute stage of the disease is over—somnolent by day, the patients may awake to an excited activity at night.

Severity of onset does not necessarily imply a fatal issue, nor should too optimistic a view be taken with regard to a case of insidious and apparently mild onset.

Statistics of the mortality of the disease have varied from 30 to 50 per cent.—figures which are, of course, quite useless in helping to make a prognosis in any individual case.

With regard to sequelæ, one can say that of the cases which recover perhaps 50 per cent. will have residual symptoms, from some of which, notably the Parkinson syndrome, they may die. Many of these sequelæ no doubt will be slight, and not in themselves disabling. It is important to remember that a case which has made an apparently perfect recovery may develop some sequel at any time in the next two years. After that period I should say the risk was negligible, and the majority of patients show evidence of incomplete recovery within twelve months.

TREATMENT.

There is unfortunately no specific treatment that has proved its value.

The Art and Practice of Medical writing : choice of words.

By GEORGE H. SIMMONS, M.D.,

and

MORRIS FISHBEIN, M.D.

Jl. American Med. Assoc., 1925.

THE use of long, technical words when short, simple words would suffice is a serious fault in scientific literature. Two comparative examples are given, the first from a modern neurologist, the second from the famous essay by James Parkinson on the “Shaking Palsy.”

(1) “There was ataxia in the upper extremities. Diadokokinesis was good in both hands. A suspicion of asynergia was aroused. There was bilateral papilledema. Hypesthesia was present in one area on the upper extremity.”

(2) “In this stage, the sleep becomes much disturbed. The tremulous motions of the limbs occur during sleep, and augment until they awaken the patient, and frequently with much agitation and alarm. The power of conveying the food to the mouth is at length so much impeded that he is obliged to consent to be fed by others.”

SOLECISMS.

Case.—“Case” is the incidence of a disease, the totality of the symptoms and of the pathologic and other conditions; “patient” is the human being, the man himself. “The case had quite a temperature,” “I put the case to bed,” “The case was taken ill three weeks ago,” “I sent the case out for a walk”—these and similar expressions are found continually in manuscripts; the error nearly always is in using “case” for “patient,” seldom the reverse.

Explore.—The following appeared in a manuscript recently received:—

“It was decided that the patient should be explored with the expectation of finding an acute appendix.”

Ambiguous Pronouns.—An author sometimes refers to himself in one place as “the writer,” in another as “the author,” in a third as “I,” and in still another as “we.” He may then use the pronoun “we” with reference to the medical profession or the public in general, and refer to the writer of some previously cited article as “the author.” Careless use of the personal pronouns makes it impossible to tell when the author is referring to himself and when to some other person. An author should refer to himself in the same terms throughout. The use of the first person singular—I, me—is the clearest and most satisfactory usage. When an author is reporting work done in conjunction with others, it is proper for him to use the pronoun “we,” provided he has stated who are represented by the “we,” so that the reader will not be confused.

Temperature and Fever.—It is incorrect to say that a patient had “no temperature.” “No fever” or “no elevation of temperature” may be used. “Temperature normal,” or “higher than normal” or “subnormal” also are satisfactory. Better still, if the temperature is normal, it should be so stated; if abnormal, it should be given in terms of the Fahrenheit or Centigrade scale.

Medical Jargon.—The peculiar usages of words which have been described are among the most frequent violations of correct use of English terms. There are, in addition, many words that have found their way into medical vocabularies with unusual meanings that are not recognized even by medical dictionaries. Such writings may properly be characterised—as medical jargon or medical slang. When these words appear in medical manuscripts or in medical conversation, they are quite unintelligible to other scientists, particularly those of foreign countries; they are not translatable; they are definitely the mark of the careless and uncultured man.

A number of these terms are given here, with the definition and the correct words following:—

Jargon	Correct Term
acute abdomen	acute conditions within the abdomen
chronic appendix	chronic appendicitis
chronic ear	chronic otitis media
collect cases of	collect instances of
Dakin's, Dakin's solution	solution of chlorinated soda
flu	influenza
lues, luetic	syphilis, syphilitic
organ or structure is negative	organ or structure is normal
pathology	pathologic change, disease
prostatic	patient with hypertrophy, inflammation, etc., of prostate
serology	changes in the blood
sleeping sickness	trypanosomiasis
suspicious of	suggestive of
specific stomach	syphilis of the stomach

Preferred Usages.—Among other usages which frequently appear in medical writings, and which, while not incorrect, are susceptible of improvement, are:—

Word	Preferred Usage
adrenal	suprarenal
amidst, amongst	amid, among
apparatuses	apparatus
autopsy	necropsy
Basedowoid	hyperthyroidism, or term descriptive of the condition
Bright's disease	chronic interstitial nephritis
cane sugar	sucrose
cure	treatment; these two words are not interchangeable
enteric fever	typhoid
Grave's disease, Basedow's disease	exophthalmic goitre
individual	person
in extremis	moribund, dying
intraspinous	intraspinal
microphotograph	photomicrograph

Word	Preferred Usage
milk-sugar	lactose
polynuclear	polymorphonuclear, when referring to leucocytes
round-celled	round cell
sacrificed	killed
spotted fever	specify disease meant, such as typhus or cerebro-spinal meningitis
x-ray	roentgen ray
x-ray picture	roentgenogram

The Success of the Abortive Treatment of Gonorrhœa.

Lancet, April 18th, 1925.

DR. MARINESCU, lecturer at the University of Bucharest, writes in the *Romania Medicala* that the successful result of abortive treatment of an incipient gonorrhœa depends upon nine conditions: (1) Treatment to follow coitus within 36 hours. (2) Normal incubation. With excessive virulence the incubation is shorter. (3) The urethral orifice not be red, nor swollen, these symptoms being the signs of great virulence. (4) No thick filaments in the urine, thin threads only are permissible. (5) The urine not turbid. (6) The microscopical examination must reveal the presence of extra-cellular gonococci only. (7) The patient must not have treated himself previously, because bad treatment endangers the success of the abortive treatment. (8) Abortive treatment must always be made by the doctor himself and never by the patient. (9) The treatment must be continued for 10 to 12 days. According to Dr. Marinescu, two therapeutic methods deserve our attention: the urethro-vesical irrigations and the urethral irrigations, or both combined. He advocates 10 per cent. argyrol solution. The first lavage serves to wash out the urethra and it has to be let out immediately, the second injection only is retained for 4 to 6 minutes. This has to be repeated 3 or 4 times a day. If the urethra becomes tender during the course of treatment, and the first part of the urine contains purulent filaments, the irrigations have to be applied less frequently. The treatment has to be continued for at least 10 to 12 days, even if the secretion becomes gonococcus-free earlier. The success of the treatment can be promoted by the administration of internal urinary antiseptics and vaccines.

Stovarsol.

Lancet, April 11th, 1925.

STOVARSOL is a comparatively new remedy.

In 1922, C. Levaditi and A. Navarro-Martin began to study the spirillicidal action of bodies related to atoxyl and prepared by Fournneau. One of the first of their series was amino-oxy-phenyl arsenite of sodium, or "189." Although this substance possesses marked therapeutic properties, the ratio of the tolerated dose to the curative dose was low, and the investigators prepared a further series of derivatives on similar lines. They found that the acetyl derivative of "189," or stovarsol, possessed much greater curative powers, and the toxic properties were much reduced.

One of the most remarkable properties of stovarsol is that it can be readily absorbed from the alimentary canal. All the curative experiments of Levaditi and Navarro-Martin were conducted by oral administration of the remedy.

In collaboration with other workers it was demonstrated that this drug, taken by the mouth, was able to protect against syphilis. These clinical experiments, of which detailed protocols have been published, were conducted with great care and thoroughness. Thus it was shown that the wives of syphilitics with primary lesions, although fully exposed to infection, could be protected by the oral administration of stovarsol alone;

2 to 4 grams may be given with safety, and the investigators claim that in stovarsol lie the properties of the ideal prophylactic substances. Its value apart from syphilis has been pointed out by many workers. Thus E. Marchaux described its use in lamblia infections and in amoebic dysentery. C. Baermann described cures effected by it in cases of frambœsia.

During the last few weeks two papers upon this question have appeared. M. Petzetakis deals with the use of the drug in amoebic dysentery. His conclusions are instructive. He found that in doses of 0.5 to 1.0 grams by mouth, stovarsol was of the greatest use in the treatment of amoebic dysentery. In the acute stages the remedy could be given with complete safety, and very beneficial results were obtained, as evidenced by a decrease in the number of stools and a diminution of pain, and other clinical manifestations of the conditions. Resistant or chronic cases responded particularly well; and in cases intolerant to emetine and in infants it is regarded by the author as invaluable. He also recommends its use as a prophylactic. These observations of Petzetakis thus supplant the work of Marchaux already quoted. Weiner Worms considers the drug from an experimental point of view. His results of the curative effects of stovarsol upon spirochætal infections in rabbits are not in strict agreement with those of the original investigators. His results are summarised in a series of tables, and the word "nichtigheilt" is applied frequently to rabbits infected with the *Spirochaeta cuniculi*. That the drug possesses marked protective powers Weiner Worms does not deny, but he implies that in order to get complete protection, there is a danger of pushing the drug to toxic limits.

It could hardly be expected that the new remedy would prove to be entirely free from the disadvantage which limited the practical value of its predecessors, the difficulty of finding a dosage adequate for the destruction of the invading organism and yet not toxic to the tissues of the host. However that may be, the convenience of oral administration is so great that the profession will welcome the introduction of this compound. If the results hitherto obtained are substantiated in wider fields there can be no doubt that the drug is a remarkable advance on former products.

Cultivation of Cholera Vibrio from Fæces.

By G. C. MAITRA,

CAPTAIN, I.M.S.,

Special Research Worker, School of Tropical Medicine and Hygiene, Calcutta,

and

J. B. BASU, M.B.,

Assistant Research Worker,

The Calcutta Medical Journal, Nov. 1924.

In a previous publication on this subject the authors mainly described and proved the advantages of using simple media for the cultivation of cholera vibrio from stool. But a uniform success under all possible conditions is scarcely the experience of a practical worker in this field. As a cholera patient passes from acute to convalescent stage and takes to ordinary food and drink bacterial flora of the gastro-intestinal tract undergoes a profound change. A sample of stool at this stage collected almost aseptically and examined fresh, shows microscopically either very few comma vibrios or none at all; and when such specimens are collected in a soiled bedpan of an Infectious Diseases Hospital and then examined hours after in a Laboratory at a distance, the complexity of the situation increases enormously. But fortunately enough most of the bacteria competing with the cholera vibrios at this stage do not grow on a plate of solid medium more vigorously than the cholera vibrios themselves, and do not produce an appreciable quantity of acid or harmful gas

(N H₂) in a comparatively sugar-free medium as the ordinary agar is.

Hence with a little practice and careful technique it is not at all difficult to obtain a few discrete vibronic colonies on ordinary agar now. But often it happens that the stool at this stage contains quite a good proportion of spreaders which not only outgrow cholera colonies but tend to cut off their oxygen supply by producing quantities of ammonia and thus kill them outright. Isolation of cholera vibrios under such conditions is never possible unless something is used to stop the activities of these spreaders. Aniline dyes or antiseptics will inhibit the spreaders, they will also kill the cholera vibrios. Confronted with this difficulty the authors had to find out something which would not be lethal to vibrios and at the same time would protect them from the inroads of their enemies. In this endeavour they were mainly guided by the biological necessity of the vibrios and their selection of particular sites and environments in the human body for prolonged existence. It was proved by Greig that the gall bladder was the favourite habitat of cholera vibrios, where they would live indefinitely unmolested by other competitors. Bile salt is naturally suggested to be the ingredient which might be useful in artificial culture. They started adding bile-salt (sodium tauro-cholate) to ordinary agar and the result was at once evident. The spreaders were checked and cholera colonies continued to grow on plates; and it is found now that $\frac{1}{2}$ per cent. sodium tauro-cholate added to ordinary agar of pH. 7.6 is quite a workable medium for cholera-cultivation both for direct plating from stool and from septone water culture, and is much preferable to such complicated media as the Dieudonne's and the McConkey's.

The Results of Attempted Rejuvenation.

(From the Vienna Correspondent of the *Lancet*,
March 28th, 1925.)

IN an interesting review covering the whole field and literature pertaining to the problem of sexual rejuvenation by means of surgical interference, Dr. Wilhelm has pointed out emphatically that the original enthusiasm over the boon conferred upon mankind by Professor Steinach and his collaborators has given way to profound silence. Professor Steinach at first believed that in the genital glands there existed two groups of cells or glands distinct as regarded their function. One was the "gland of puberty," which was supposed to be subject to hypertrophy if the other part, the "progenitory gland," was eliminated by ligation of the vas deferens. Several medical men of ripe age, amongst them Professor Zeissl (who died recently in Vienna), underwent this operation and published the results obtained. Professor Romeis is also strongly opposed to the views of Professor Steinach. Professor Zeissl published in the *Wiener Klinische Wochenschrift* an auto-biographical account of the operation and denied absolutely that it had any of the effects of rejuvenation of his own body, as had been claimed by the "youth restorers." In all the cases of rejuvenation of rats, reported by Steinach, Kammerer, and Voronoff, an improvement of the general condition could be observed after the operation, but the effect was only temporary. After some time the old conditions returned, in some instances even there was distinct deterioration. The return or increase of sexual desire and function could not be proved to be other than a psychic one. Professor Leschke, of Berlin, was able to demonstrate that the ageing of human beings was dependent not only on the interstitial substance of the testicles, but also on the other inner secretory glands. When it was finally shown by Harms and Romeis that an old male rat could be made to produce long glossy hair, not only by transplantation of testicles, but also of fragments of liver tissue, it became evident that a large proportion of all the "rejuvenation" symptoms were simply caused

by reabsorption of non-specific products of metabolism from the transplanted material. Also the use of X-rays and of diathermy on the female genital glands, so much in vogue for some time as methods of rejuvenation of the female organism, have become quite obsolete; nor have the original attempts at curing sexual perversion (homosexualism, sadism) by means of transplantation of genital gland tissue been successful. Dr. Lichtenstern reports on 22 cases of such attempts, and is forced to admit that the effect had been rather "overrated." It is therefore questionable whether we are altogether on the right track in trying to obtain a "prolongation of youth" by these means, or whether it is only a faulty technique that is responsible for the unfavourable results.

A New Method of Blood-Letting.

Practitioner, April 1925, p. 310.

C. S. DANZER has worked out a new technique which causes little discomfort to the patient. Two 20-cm. Ricord or Luer syringes are connected by means of rubber tubing with two ends of a three-way stopcock. The third end of the latter is connected by a piece of tubing to the needle, the lumen of which must not be too narrow. The vein is punctured in the usual way, and one syringe is filled. The stopcock is turned so that the other syringe is in series with the needle, and the blood is aspirated into the second syringe. Meanwhile an assistant disconnects the first syringe, empties the blood into a basin of warm water, washes the syringe, and reconnects it. The stopcock is turned back to its original position, so that syringe number one is connected with the needle and blood is again aspirated. Meanwhile syringe number two is emptied of its blood, washed, and connected again. In this way a fairly large quantity of blood can be removed in a few minutes, with practically no discomfort to the patient.—(*Medical Journal and Record* (New York), February 4, 1925, p. 150.)

Food Poisoning.

British Med. J., May 9, 1925, p. 897.

THE Medical Research Council has issued a special report by Dr. W. G. Savage and Mr. Bruce White on food poisoning, founded on a study of 100 recent outbreaks in England.

By far the commonest cause of food poisoning in England is infection of food by living *Salmonella* bacteria or by the toxins of these microbes. *Salmonella* bacteria multiply rapidly in food without causing any obvious decomposition, and they secrete powerful endotoxins capable of resisting temperatures as high as 100° C. In 20 of the 100 outbreaks recorded in this report, living *Salmonella* bacteria were proved to be the agents of infection, and in 14 of these 20 outbreaks *B. aertrycke* was found. The isolation of these bacilli is difficult. In six of these outbreaks the bacilli were only captured from material obtained at postmortem examinations.

Food in which *Salmonella* bacteria have grown may continue to be poisonous after the bacilli themselves have been destroyed, because the toxin is more resistant to heat than the living cells. Food poisoning by toxins of the *Salmonella* bacteria is the most difficult of all to analyse, because ingestion of these toxins leaves no specific stamp upon the body tissues and agglutinins do not appear in the blood serum. Feeding experiments on animals are not often successful, because animals are exceptionally resistant to these toxins. A new method of study is by feeding animals with large quantities, killing the animal nine to twelve hours afterwards, and examining the stomach and intestines for evidence of inflammatory reaction. Another new method is the demonstration of the production of specific agglutinins to the *Salmonella* bacilli through the injection into animals, of suitable emulsions of the

incriminated food. By these methods of investigation the authors of this report have satisfied themselves that 17 out of the 100 outbreaks should be ascribed to *Salmonella* toxins.

Four of the outbreaks were caused by bacteria of the dysentery group which may cause outbreaks of food poisoning indistinguishable in their clinical characters from *Salmonella* infections.

The outbreak of botulism at Loch Marce is dealt with. The responsible food was almost invariably wholesome as judged by sight, taste and smell; tinned food constituted 42 per cent. of the whole. Nearly all the outbreaks from undestroyed bacterial toxin arose from canned food, whereas "made up" meat was much the commonest vehicle for the living bacilli, and milk products for the remainder. Often all who took the incriminated food were affected.

A provisional diagnosis of botulism must be based on symptoms and epidemiological factors; the definite diagnosis is the task of the bacteriologist. The characteristic symptoms are eye disturbances such as double vision; throat symptoms, such as difficulty in swallowing and talking; general muscular weakness. Pain is absent, the cardinal symptoms of *Salmonella* type of infection are not found, constipation rather than diarrhoea is the rule. Fever is rare. Mentality and consciousness are usually clear to the end.

B. botulinus is an anaerobe and the food vehicle must be such as will allow growth in the absence of oxygen. *B. botulinus* is a proteolytic anaerobe, and will originate decomposition changes in the food if it multiplies sufficiently to yield toxin, a feature which distinguishes it from the behaviour of *Salmonella* bacteria which do not cause any evident decomposition. Though the food is altered the changes may be slight, and only detected by an expert. At Loch Marce, they were missed altogether. Owing to the high potency of *B. botulinus* toxin, nearly everyone who partakes of food infected with this organism becomes ill. To the *Salmonella* type of infection some individuals are much more resistant than others, and may escape.

Practically nothing is known at present of the way in which the bacteria of food poisoning get into food. The *Salmonella* bacteria are not present in the normal excreta of man or animals. The germs may have a habitat outside the body, infection may come from a human case or infection may come from an animal source—either from the meat or milk of an infected animal being used for food or due to infection of previously wholesome food with bacilli from an infected animal.

The authors conclude that in the majority of the 100 outbreaks reported the food was originally sound, but became infected with *Salmonella* bacteria from outside sources. The particular channel of contamination in most of the outbreaks remained uncertain.

On the Relative Value of Symptoms and Physical Signs in the Early Diagnosis of Pulmonary Tuberculosis.

This important subject is dealt with in the *Practitioner*, April 1925, by Dr. D. G. Macleod Munro, M.B., M.R.C.P., Deputy Commissioner of Medical Services for Tuberculosis to the Ministry of Pensions.

Some extracts from his valuable paper are given:—

The time is ripe to seek an adjustment of values between the two chief factors in the early diagnosis of pulmonary tuberculosis—namely, the symptomatology and physical signs of the disease at this stage. Hitherto, inspection of the chest has been rather a perfunctory affair and the virtues of palpation limited to vocal fremitus—now regarded as a diagnostic asset of nominal value. Now that special attention is being paid to the muscle reflex, which results in what is known as "lagging," the presence of which especially at an apex strongly suggests active mischief, although percussion and auscultation may give no indication of this, inspection and palpation assume a more important role.

The information conveyed by inspection in these cases may be greatly reinforced by light finger-tip palpation, by means of which evidence of localized reflex muscle spasm especially as affecting the sternomastoid, the scaleni, and the upper pectorals may be detected. The trained finger appreciates in such cases a sense of muscle resistance in contradistinction to the smooth and more elastic sensation of normal muscle tension. Then, too, trophic changes in the muscles of the shoulder girdle and the state of the subcutaneous tissues may be similarly recognized. In the opinion of some experts, indeed, light touch palpation has very largely replaced percussion as an aid to diagnosis. In this connection it must be noted that one may find dystrophy of the shoulder girdle muscles on one side—that on which the disease has been of some standing—and reflex muscle spasm on the opposite side, where the disease is active and more recent.

Percussion to be of any real value must be very light. Local changes in the percussion note, especially at the apex of a lung convey nothing as to the presence of an active tuberculous lesion or indeed, that the lesion, if such exists, is tubercular at all.

Alteration in the percussion note is more significant if found at the left apex, and, further, it is often useful to percuss from below upwards. The value of "respiratory" percussion also must not be overlooked in doubtful cases.

It has often been the case that on finding limited and apparently abnormal signs at an apex or elsewhere, signs indicating some aberration from the so-called normal, we have promptly banished the unfortunate victim to a sanatorium, after which, despite the fact that he may have been non-tuberculous, he is inevitably branded with the stigma of tuberculosis with consequent loss of economic value, not to speak of the serious family disruption occasioned by his course of treatment. I have no hesitation in saying that a by no means insignificant proportion of persons undergoing sanatorium treatment may be found not to be suffering from pulmonary tuberculosis at all.

No physical signs whatever suggestive of pulmonary tuberculosis may have been found after the most careful examination, and yet the disease has declared itself by a sharp hæmoptysis. It may quite well have been that in some of these cases the history and symptomatic evidence had not been given their due importance.

We can affirm that pulmonary tuberculosis cannot be said to be present in an active form without some of the symptoms of toxæmia. It must be noted, however, as will be shown later, that tuberculosis cannot be held responsible for every unexplained toxæmia.

The symptoms may not have been sufficiently obvious to call the patient's attention to the matter at all, and it is just in such cases that the closest scrutiny of the history of the case may furnish just that sufficiency of evidence to turn suspicion into something more tangible. The patient's appetite may have become capricious, or he may have suffered a good deal from flatulence, for which he is unable to account. He may have been having an unaccustomed sense of "tiredness" in the morning, or there may have been recurring headaches, possibly some backache, but not sufficient to indicate to him that he has been febrile.

The symptom-complex of toxæmia is much the same from whatever source of infection it may be derived, the result is shown by such symptoms as malaise and lassitude, nervous instability, tachycardia, fever, and night sweats. This group of symptoms, important though they are, cannot in themselves be regarded as pathognomonic of pulmonary tuberculosis, and other probable causes of infection must be eliminated.

The patient feels more easily tired than usual. Languor is characteristically present in the morning, passing off as the day proceeds, but returning later.

Fever.—The presence of fever is of the greatest value. It has been found that in the majority of healthy persons the average early morning temperature is approximately 97.2° F. to 97.4° F., rising to a maximum

of 98.6° F. in the early afternoon. Some variation beyond these strict limits are met with of course in individual cases, and are often dependent upon certain extraneous factors. If certain simple precautions are taken, oral temperature records are quite trustworthy except in the case of mouth-breathers. The thermometer should be retained in the mouth for at least seven minutes. Temperatures should not be taken immediately after the patient returns indoors, after exposure to cold wind nor after partaking of a hot meal. The maximum temperature period shows great variability in different persons. To ascertain this maximum period with any accuracy in a given case it is necessary to take the temperature every two hours. The first recorded temperature for the day ought not to be, as is often the case, after the patient has got up and dressed, but as early as possible in the morning before rising. Further, it must be remembered that there is a normal diurnal variation in temperature of about 1.5° F. as a result of the natural ebb and flow of the body heat.

In early pulmonary tuberculosis it may be found that the early morning temperature is 98° F. and maximum record for the day 99.2° F. or 99.4° F. A continuous temperature record should extend over three or four weeks in any case of suspected early tuberculosis.

The early morning temperature may also be abnormally low, e.g., 96.8° F., and in such cases a rise from this point to 98.8° F. in the early afternoon must be regarded with suspicion, if occurring regularly and from no known cause.

But assuming that the temperature shows evidence of toxæmia and there are no other definite signs or symptoms to support a diagnosis of pulmonary tuberculosis a further analysis will have to be made to exclude other possible causes. Among these must be mentioned sinusitis, appendicular trouble, tonsillar infections, septic teeth, bronchiectasis and similar localized infections.

In persons of highly strung nervous temperament, there are sometimes quite noticeable variations in the temperature curve.

Dr. Munro attaches much importance to an early morning temperature—taken before rising—which is consistently a little above the average mean. Of additional assistance to diagnosis is the increase of temperature caused by a definite amount of exercise, with a control. In a healthy person there is always a temporary rise in temperature—sometimes a considerable one—after exercise, this is usually quite evanescent and within half-an-hour or so the temperature returns to normal. This is not so in the case of tuberculous persons. The decline of the temperature to normal limits is delayed and it may remain elevated for two or three hours.

The absence of fever does not necessarily rule out the possibility of pulmonary tuberculosis.

Tachycardia, which is of frequent occurrence in early tuberculosis—Fishberg puts it at 90 per cent. of incipient cases—is hardly ever a subjective symptom.

A pulse rate out of all proportion to any febrile condition present is a very common and reliable symptom of early tuberculosis in an active state, and the pulse rate may be notably increased on the slightest excitement or even after a fit of coughing. The increased pulse rate after exercise, falls much more slowly than in health.

Hypotension will be found to be present in a good many cases.

Gastro-Intestinal Symptoms.—Capriciousness of appetite is common, and it is characteristic too of the disease that with a temperature of considerable altitude there is often no loss of appetite, such as is to be noted in more febrile states. The development and persistence of gastritis of varying severity in a young person, without known cause, especially if there be any additional evidence of systemic disturbances, is to be regarded with suspicion.

While progressive loss of weight has considerable significance, it must not be forgotten that there may be

quite noticeable fluctuations in weight up to the age of twenty-five or more.

The group of symptoms covered by the terms *neurasthenia* and *psychasthenia* may be the only evidences of an early pulmonary tuberculosis. These may continue for a number of years, sometimes without any overt signs of pulmonary trouble. Perhaps the most characteristic is languor, and the persistent sense of tiredness, the disinclination to take up any task, and the inability to concentrate on any work undertaken. Sometimes, too, there is marked mental irritability and changefulness of mood. In addition, we may often note headache, fleeting spinal pains, and giddiness. Pain under one or other clavicle is not infrequently complained of, and may be elicited on deep pressure.

Conclusions.—Pulmonary tuberculosis may masquerade as an affection of each of the great systems of the body with no signs or symptoms in any way referable to the lungs. There is no other disease which, very often under the outward guise of ordinary health, can present so protean an array of symptoms often apparently trivial in themselves. Of the several symptoms discussed one only may be present in a given case, or the patient may present the most disconcerting variety of symptoms, each of which has to be tracked to its lair, so to speak. In none of these cases it is assumed can any assistance be rendered by the presence of cough, hæmoptysis, or pleurisy, nor does X-ray examination at this stage yield any useful information. The complement fixation test may or may not be of some assistance.

A diagnosis can sometimes be arrived at long before one could be made by ordinary physical examination of the chest, and the confirmatory evidence of sputum and X-ray findings make the diagnosis evident to the most casual observer.

Nova et Vetera.

Eighteenth Century Medical Practice in England.

British Med. Jl., May 2nd, 1925, p. 853.

In the Sloane MSS. (4077) there are two letters from Dr. Alban Thomas of Cardigan to Sir Hans Sloane, giving the history of two cases and asking for advice as to treatment.

The second letter runs as follows:

Most Hon'ble Sir,

I have presumed upon the foot of former Acquaintance with your honor to recommend the Case of this Revd. and worthy Gentleman to your perusal, well knowing you to have had more experience than any one of the Faculty now living not only in Cases of this inveterate nature but all others which Humane Bodies are lyable to. Be plased therefore to know that this gentleman is of a pretty gross habit of Body but free as yet from any hydropical Symptoms, of a moist phlegmatick Constitution no way Subject hitherto to any other Inflammatory feavers but the Small-pox which he hath given an Acct of in his Letter to Mr. Gell the Bearer hereof: He is Scorbutick in the highest degree but whether it approaches towards the *Læpra Græcorum* must be determined by your riper Judgement as also whether some preparation from the Viper may not be of use to him together with due Evacuations and a long Continuance of proper Antiscorbutick Alteratives, and your wonted Candour and Humanity will give me leave to acquaint you that I have used the unguentum Citrinum upon such Eruptions with good success in ordinary Constitutions but never without putting them under a Course of Physick for at least Six weeks together first. I heartily rejoyce that you Still, in Spight of Age honourably triumph at the head of the Profession: may you long continue so for the publick good: and I desire you would recollect me to be Your old Sincere friend and most obliged humble Servt.

New Castle in Emlyn

ALBAN THOMAS.

Novr 13, 1738

Sir Hans Sloane's directions for the treatment of this

case, written in Latin in a crabbed hand and much contracted, are preserved with the letter. Dr. F. William Cock has elucidated them. The original runs as follows:—

Venesect. fol anthem. pulv. viper. bezoardici pts h. s. sine theriaca mane cum apozem: sudorific. Elect. lenitiv. pro re nata merc. precipitat. et aq. miner. purge.

Rendered freely into English the prescription would read:

Bleed the patient. At bedtime let him have a powder made of equal parts of camomile leaves, powder of vipers, and bezoar stone. In the early morning let him have a sweating draught without laudanum. As a laxative, let him take the compound electuary of senna as required. To purge, give mercurial precipitate and mineral water.

Morbidity versus Mortality.

DEATH rates are the usually accepted indications of the unhealthiness of a community, but sickness rates should also be taken into account.

Sydenstriker in the *Public Health Reports of the United States* for February 13th, 1925, deals with this aspect of the question. He dealt with a population group of about 8,500 persons over a period of two years. He found that for every death there were about a hundred cases of sickness, more than half of the illness being due to respiratory diseases.

Diseases of the digestive system were responsible for a sickness rate of 117 per mille while their mortality rate was less than 1 per mille. The diseases against which public health effort is specially directed caused 11 per cent. of all the illness of the community, which was investigated.

Deaths from disease occur chiefly in infancy and old age, but illness is fairly uniformly distributed throughout the whole life.

The author estimates that a million of the wage earners of the United States are off work on each day of the year and that the cost to the country is more than a hundred million pounds yearly. A similar survey for a number of typical communities in India would be of great value: we know in a general way how appalling is the amount of disease and death in India. Accurate figures showing the disease rate and the cost of disease to the community would make the problem more definite and precise and would help to arouse a sense of dissatisfaction with the existing state of affairs.

Tuberculosis.

THE correspondent of the *Journal of the American Medical Association*, in the number for 9th May, 1925, gives an interesting report of the discussion on tuberculosis which took place recently at the Pediatric Society of Berlin.

Professor Bessau of Leipzig holds that there is a specific immunity to tuberculosis, this is not based on antibodies but is related to hypersusceptibility which is in some way associated with certain cells of the body ("tuberculoocytes"). These cells are believed to be formed in response to the stimulus of tuberculin, and the degree of immunity which is developed is proportional to the capacity of the animal to form the tuberculoocytes.

In treatment the aim is to cause mild focal reaction without general reactions. Intravenous injections of tuberculin (apparently any kind) in a dilution of one in one thousand million are capable of causing suitable focal reactions.

Langer of Charlottenburg immunized guinea-pigs by intracutaneous injections of young strains of killed tubercle bacilli and he has employed this method also in young children who give a positive tuberculin reaction six weeks after inoculation.

Professor Engel of Dortmund agrees with the orthodox view that most children get tuberculosis which seldom causes obvious signs of the disease, and which may even cause no discoverable anatomical lesion.

He divides the infection of childhood into two groups:—

(1) Micro-infection or occult tuberculosis with non-discoverable lesion and usually overlooked.

(2) Macro-infections in which there is a discoverable lesion either of the bronchial glands or elsewhere.

Lesions of the bronchial glands often cannot be distinguished by physical examination, even radiographic methods often mislead.

Micro-infections can only be detected by the effect which they have on the sensitiveness of the body to tuberculin, clinical manifestations may be absent or may be indistinguishable from other conditions which cause malnutrition and fever.

The Toxic Factor in Disease, with Special Reference to Chronic Rheumatic Conditions and Diabetes.

By SIR WILLIAM WILLCOX, K.C.I.E., C.B.,

C.M.G., M.D., F.R.C.P.,

Medical Adviser to the Home Office.

Practitioner, May 1925, p. 326.

We give a few extracts from this very important article:—

The toxic factor as a cause of the symptoms of disease is generally accepted in the case of those diseases of which the specific cause is known.

Diseases where the proof of a specific causal organism is less clearly demonstrable include by far the largest group of diseases, and most of the common ailments come under this category. For example:—

Chronic rheumatic conditions, diabetes, hyperpiesia and arterial disease, various forms of secondary anaemia and possibly pernicious anaemia, many skin diseases, retinitis and many pathological eye conditions, asthma, gout, exophthalmic goitre, colitis, appendicitis, gastric and duodenal ulcer, some diseases of the central nervous system, such as combined sclerosis.

In most of these conditions careful search will reveal some definite toxin, and in many cases a definite focus of bacterial sepsis can be found.

Focal Sepsis.—By this is meant a part of the body in which a definite bacterial infection is present and which acts as a disturbing centre for toxins. Focal sepsis may act as a cause of disease by virtue of the toxins being carried to other parts of the body and setting up a diseased condition by their direct action.

Symbiosis may have an important bearing in determining the type of disease resulting from focal sepsis. Thus the absorption of toxins from an infection of one kind of organism may so lower the resistance of the body that another organism may set up disease. The streptococcal toxæmia of dental sepsis may lead indirectly to the recurrence of staphylococcal infections, such as boils or carbuncles, and removal of the streptococcal focus is often followed by a cure of the recurrent staphylococcal infection.

Sensitization to the toxins from focal sepsis is a most important factor in causation of disease. In this condition the constant stream of toxins flowing into the blood stream so lowers the resistance that disease of a particular type results. Examples of this are to be seen in certain erythemata and recurring urticarial eruptions, in asthma, gout, and angio-neurotic oedema. These conditions are sometimes due to the toxic effects of focal sepsis coupled with a sensitized condition. It is often found in such cases that great hypersensitization exists to a vaccine prepared from the specific focus and in cases of this type vaccine therapy if used at all must be applied with the utmost caution, the initial doses being extremely small.

It seems likely that the occurrence of certain cases of nephritis, and of toxic eye conditions and probably many other diseases of obscure causation, will be explained by the sensitization set up by the toxins of some focus of sepsis.

Chronic rheumatic conditions of non-specific origin include the various forms of fibrositis, such as inflammatory conditions of aponeuroses (muscular rheumatism), tendons and ligaments; panniculitis, bursitis, finger pads, and Heberden's nodes; the various forms of arthritis, perineuritis occurring as sciatica, brachial neuritis, etc., are common examples.

"Chronic rheumatism" is probably the commonest disease at the present day, and it heads the list of incapacitating diseases as judged by the National Health Insurance statistics. The most important aetiological factor in chronic rheumatic conditions is probably the toxic factor. In almost all cases careful search will reveal some focus of infection. In most cases the organisms present in the focus of infection will be streptococci usually belonging to the viridan group. It cannot be too strongly appreciated that chronic rheumatic conditions are not a primary disease but simply one group of manifestations of a toxæmia usually of streptococcal origin.

In every case of "chronic rheumatism" careful search should be made for a focus of infection. Dental sepsis is the commonest cause, and a clinical examination of the teeth should be supplemented by careful radiographic examination. The tonsil, naso-pharynx, maxillary, antra and accessory sinuses should be carefully examined. Bacteriological examinations of the stools and colon washings and of the urine should be carried out. Evidence of an infection with streptococci of the viridin group is almost always found.

Infected teeth should be removed, and this is most essential in those showing apical infection. Tonsils if badly infected should be enucleated under proper surgical safeguards, unless their condition is such that medical treatment is likely to be followed by removal of the focus of infection. Infected antra will require surgical treatment. Where evidence of colon infection is present, either from clinical or bacteriological examination, colon lavage is of value. The presence of colon toxæmia is usually shown by a marked excess of indican in the urine, and it is most important that this test should be applied in cases of chronic rheumatism. Where the rheumatic condition is of long standing vaccine treatment is advisable, but only when the focal sepsis has been adequately dealt with. The best results are obtained with combined vaccine made from the several foci of infection.

It is important to remember that in most cases where a primary infection occurs in the teeth or naso-pharynx, the colon becomes secondarily infected. It is therefore generally advisable that pathogenic streptococci from the colon should accompany the streptococci from the teeth or tonsils. A convenient strength of vaccine is fifty millions combined streptococci per c.cm., but in cases where there are symptoms of severe toxæmia a strength much less than this, e.g., from one to five millions per c.cm., should be used at first.

In Sir William's hospital practice the routine treatment in arthritis is as follows:—

Guaicol carbonate, grains 10 three times daily, and to this a few grains of aceto-salicylic acid are added with each dose if much pain be present.

Also tincture of iodine (French Pharmacopœia, without potassium iodide) m.iv, in a wineglassful of milk or water, three times daily, after meals, is given, the dose being increased to 6 or 8 minims.

Local treatment of the affected parts by hot applications such as iodine poultices, radiant heat, ionization or diathermy is advisable. In chronic cases of arthritis the rubbing in of an ointment composed of Scott's dressing diluted with two or three parts of lanoline is very helpful, and this may be applied night and morning, the joint being covered by a bandage.

Infection as a Cause of Diabetes.—It is well-known that severe glycosuria may result from the toxæmia of acute infections.

It is an established fact that the internal secretory cells in the islands of Langerhans are susceptible to toxic influences, and, in every case of diabetes, careful search should be made for chronic infections resulting from focal sepsis.

Any focal sepsis should be dealt with at this stage by appropriate surgical measures. After the preliminary treatment of the diabetes has been successfully carried out and the patient is free from glycosuria and acetonaemia, there is no risk in the administration of an anæsthetic for the surgical treatment of the focal sepsis. Local anæsthesia, or general anæsthesia with gas, or gas and oxygen, or ether, may be given. Chloroform should not be administered to diabetic patients owing to its toxic effects.

The removal of focal sepsis is usually followed by an immediate transient fall in the carbohydrate tolerance, and glycosuria frequently recurs. This is due not to the effect of the anæsthetic but to the auto-inoculation resulting from the operation. After the removal of focal sepsis in a few days the carbohydrate tolerance usually rises to a figure considerably higher than that before operation. In some cases the rise has been so pronounced that the carbohydrate tolerance has risen to a figure approaching the normal and further treatment has been unnecessary.

In cases of focal sepsis of long duration, it is probable that great damage to the pancreas has already occurred, so that great recovery in the carbohydrate tolerance cannot be expected. The removal of the focal infection is, however, a safeguard against further pancreatic damage, and is almost always followed by some rise in the carbohydrate tolerance.

The principle underlying the treatment of the above conditions should be based on the removal or minimising of the causal toxæmia. Other methods of treatment, such as local treatment in rheumatic conditions, dietetic and insulin treatment in diabetes are of great importance and should supplement that of the causal toxæmia.

Reviews.

THE TECHNIC OF LOCAL ANÆSTHESIA.—By Arthur E. Hertzler, A.M., M.D., Ph.D., LL.D., F.A.C.S. Third Edition. St. Louis: The C. V. Mosby Company, 1925. Pp. 272, with 140 illustrations. Price, \$5.50.

THE author of this book is best known to English readers for his work on the thyroid gland in which he records his practice and observations in.... "a small country hospital." Possibly it is the limitations of such a hospital that has led to his extensive use of local anaesthesia. Be that as it may, there is no doubt that the conditions prevailing in most Indian hospitals are such as to call for a more extended use of local anaesthesia. Trained anaesthetists are few and far between and even among these it is rare to find one capable of giving open ether. Chloroform, owing to the danger of decomposition in a hot climate, is more dangerous than in a temperate one. Local anaesthesia has therefore a wider field of application than in other countries.

In this volume we find the necessary guidance, based on experience, to enable any surgeon to pick out those cases where local anaesthesia is the method of choice, and those where it is possible when general anaesthesia is contraindicated or not available. The instructions are so clear and defined that there can be little excuse for making vast demands on the patient's fortitude. The limitations of this procedure are described as fully as its possibilities. We feel that this book is not written by a wild enthusiast for local anaesthesia, but by an experienced surgeon who selects his methods, solely guided by the interests of his patient.

The book opens with a brief description and criticism of drugs available, followed by a general description of the technic of administration. The chief characteristic of the latter is its simplicity and absence of special apparatus. A brief description of general operations is followed by a series of chapters devoted to regions and the operations pertaining thereto. Each chapter opens with the neural anatomy of the region, followed by detailed instructions for each operation performed in that particular area. Thus a typical chapter is that on operations of the face, jaw and tongue. After a general discussion of the problems peculiar to this region, several pages are devoted to the neural anatomy with illustrations of the fifth nerve and its branches. Then come instructions for operations on the orbit, frontal sinus, soft parts of the face, upper jaw, extraction of teeth, tumours of alveolar process, infections of the antrum, resection of the jaw, operations on lower jaw, tumours of the lower jaw, excision of cervical lymph glands, excision of the jaw, operations on the tongue and tumours of the floor of the mouth, buccal soft parts and lips.

There are seventeen chapters of this type so that the ground is amply covered.

The chapter on abdominal operations includes wise advice when to abandon local anaesthesia and substitute general and also when to combine the two. The author definitely sets himself against anything in the nature of "stunts." His descriptions include a new method of injecting the gasserian ganglion. There is also a chapter on sacral blocking paravertebral and spinal anaesthesia. He only admits one indication for paravertebral blocking, namely operations on the thoracic oesophagus. Anywhere else it is a "stunt."

We learn that to do a radical mastoid under local anaesthesia requires "plenty of time and the enthusiasm of youth."

The book is eminently readable because of the author's easy style and somewhat caustic wit. For example, in condemning a special chair for paravertebral blocking devised by an enthusiast he remarks "Looking at the chair one would think it was designed for the cure of chronic constipation. The patients in whom I have used paravertebral anaesthesia have been too sick to sit up and their bellies too sore to make it possible for them to imitate the shivering dog."

We do not know any book giving sounder advice and clearer instructions. We confidently recommend it to all interested in the subject. The printing, illustrations and binding are typical of the best American publications, but there are several printer's errors which we trust will be rectified in the next edition.

FORENSIC MEDICINE.—By Sydney Smith, M.D., D.P.H., Principal Medico-legal Expert, Egyptian Government Service; and Professor of Forensic Medicine in the Royal School of Medicine and Law, Cairo. London: J. & A. Churchill, 1925. Pp. 498, with 117 illustrations. Price 21s. net.

COMPARATIVELY few works on forensic medicine have appeared since the publication of Taylor's "Manual of Medical Jurisprudence" in 1844.

The appearance of a new text-book on the subject by an experienced teacher is therefore specially welcome. The book throughout bears the stamp of the author's experience and original study.

The distinctive feature of the book is its pointedness. The reader learns at once what to look for, where to look for it and how to assess the value of appearances as evidence. The author's large experience has enabled him to reassess, in the book, the relative value of time-honoured appearances, as evidence, and to assign them their proper places in the light of such experience. Further contribution of an original and practical nature from the author's investigations have materially contributed to the value of chapters on wounds, injuries, violent deaths, sexual offences and infanticide.

Much original matter and many practical hints will be found in these chapters. Students and practitioners in India would find it necessary to supplement their reading, by knowledge concern-

ing medico-legal matters peculiar to the country, from books on the subject, but apart from this the book may be safely recommended as an up-to-date treatise on forensic medicine. The book is concisely written and excellently illustrated. The book would be found particularly valuable by those whose duty involves the sifting of medico-legal evidence and the giving of evidence in court.

THE INHERITANCE OF MENTAL DISEASES.—By Abraham Myerson. Baltimore: Williams & Wilkins Co., 1925. English Agents: Messrs. Baillière, Tindall & Cox, London. Pp. 336. Price, 25s. net.

THIS book appeals to a wide field of readers and workers. The educationalist, the psychiatrist, the economist, and all those interested in the health and welfare of their community will find in it much food for thought. Even though they find they cannot concur in all the views propounded by the author, they will gain much benefit and useful knowledge from a perusal of his work, new views will be brought to their notice, new light thrown upon old ones.

The manner in which the term "insanity" is discussed in chapter I is delightful reading and should be an eye-opener to many and bring them to a very different opinion regarding mental diseases from that they hold at present when they class them all under the one generic term "insanity."

In chapter III he still further develops his thesis grouping mental diseases on what he terms a "biological and logical basis. The phrase is a happy one and in his hands the theme is admirably developed and teems with information. The rest of part I is devoted to a discussion of the psychoneuroses and epilepsy, feeble-mindedness and certain mental diseases.

In part II, we attain at last to the main object of the book and justify its title. Here the reader is confronted with a huge number of statistics and records of families which provide most interesting and informative reading when taken in conjunction with the author's summaries. On the whole he brings forth much evidence in support of his statement that there is a possibility that mental diseases are caused by unknown environmental agents whose effects persist over two or more generations and from which a stock may die or recover.

Finally the larger problem that is involved by the issue of heredity or disease is dealt with. Here the author plumps whole-heartedly for disease as opposed to heredity and opposes strenuously the doctrines of eugenicists who condemn hygiene as being bad for the stock. He considers adverse environmental conditions to be very much more responsible than is generally supposed for conditions now usually considered to be due to heredity and claims that if his views be correct then hygiene is the salvation of all nations and eugenicists naught but false prophets whose doctrines but hasten a nation's progress on the path to destruction, as by accepting them hygiene is indicted and efforts to eliminate adverse environmental conditions are diminished, even if they do not wholly cease.

It is a book that cannot be taken up and skimmed through. It must be read at leisure and each part thoroughly assimilated and grasped before a subsequent one is attempted. The reader will gain a fund of information from his perusal of its pages and much food for thought on the new aspect of the inheritance of mental diseases.

SURGICAL OPERATIONS. A TEXT-BOOK FOR NURSES.—By E. W. Hey Groves, M.D., B.Sc., M.S., F.R.C.S. Second Edition. London: Oxford University Press. Pp. 255. Price, 21s. net.

THAT a second edition of this excellent little work should have been called for so soon after the appearance of the first edition is not surprising in view of the admirable fashion in which it serves the purpose for which it was designed.

Although principally intended for the use of nurses the book will repay the student who is commencing his clinical studies the trouble of reading it.

In the first chapter the general organisation of the operating unit is discussed with special reference to the all-important subject of sterilisation. This section is clearly and briefly written; more stress might perhaps be laid on the danger of overloading the steriliser drums.

It cannot be too often repeated that though the temperature at the outside of the drum may be and often is 121°C ., that at the centre of the drum may be only 95°C .

The use of a mixture of methylene-blue and anti-febrin in a proportion of 2 grains to 1 ounce is recommended as a safeguard; the mixture is said to remain white up to a temperature of 230°F . The reviewer has tried this and found it highly unreliable. In any case it must be placed in sealed glass tubes.

The remainder of the book is devoted to a brief account of all the common operations of surgery, the instruments used and the technique employed together with a short account of the indications for operation.

The book ends with an illustrated catalogue of the common instruments in use at the present day.

The illustrations are numerous and admirably clear, the style simple and lucid, as we should have expected in the case of a work by a master-craftsman writing about his own art.

OPERATIVE SURGERY.—By J. Shelton Horsley, M.D., F.A.C.S. Second Edition. St. Louis: The C. V. Mosby Co., 1924. Pp. 784, with 666 original illustrations. Price, \$12.50.

In the great majority of books on operative surgery all the known methods are described and but little attempt is made clearly to indicate the best method according to the experience of the author.

In this book which covers the whole range of operative surgery, exclusive of gynaecology, Dr. Horsley only describes in detail the techniques, which in view of his experience he deems best, thus considerably increasing the value of the work as a guide to the inexperienced surgeon.

Throughout he insists that in extirpating or correcting pathological conditions one should always keep in view the restoration of the physiology of the tissues or organs, and this principle is very apparent in the method of pyloroplasty which he has devised.

In chapter 2 he discusses surgical drainage and states that as a result of the irritation of the drainage material there is a reversal of the local lymph circulation with outpouring of serum.

The chapters on aneurisms and suturing of blood vessels are particularly clear and well illustrated.

Quite an unusual feature of this work is a chapter devoted to the principles underlying operations for malignant tumours.

The following new operations are incorporated in the text:—The lymphaticostomy of Costain for diffuse septic peritonitis, Stookey's operation for innervating paralysed muscles, Finney's pylorotomy, Graham's pulmonary lobectomy, Cutler's valvotomy for mitral stenosis, the operation for angina pectoris of Coffing and Brown, the chordotomy of Frazier, and Kerr's intestinal resection.

We cannot criticise, but can only admire, welcome, and recommend the second edition of this interesting book by so thoughtful and experienced a surgeon.

The book is beautifully illustrated and the type large and clear.

THE PRACTICAL MEDICINE SERIES. Vol. 2. GENERAL SURGERY.—Edited by A. J. Ochsner, M.D., F.R.M.S., LL.D., F.A.C.S., F.R.C.S., Jr. (Hon.). Series 1924. Chicago: The Year Book Publishers. Pp. 706. Price, \$3.00.

A VERY comprehensive review of the past year's important literature of clinical surgery under the

distinguished editorship of the President of the American College of Surgeons.

There is a very interesting address on acute osteomyelitis by Dr. Ochsner, in which he stresses the importance of early diagnosis, and recommends early free incision of the periosteum combined with a moist boric acid alcohol dressing with an electric light over it to ensure warmth. He condemns the practice of chiselling away bone in the acute cases, as it produces necrosis of good bone and spreads the infection, and he maintains that simple free incision of the periosteum is all that is necessary in the primary treatment, as it changes the direction of the lymph stream with a consequent outpouring of lymph in the dressings.

He mentions a very instructive case in which by simply incising the periosteum he was able to save a metatarsal bone which was black from end to end without the formation of any sequestrum.

In the section on anaesthetics Keates states that he has never used or seen used any other general anaesthetic but chloroform, and that open ether would be out of the question in the hot weather in India.

We would like to correct the impression that ether is not used in India, as for the past two years it has been the general anaesthetic used throughout the year, by the open method, at the Presidency General Hospital, Calcutta.

Of great interest to surgeons in India are the statistics quoted by Walton on the effect of heat on operations for exophthalmic goitre. He states that from statistics of over ten years, the operative mortality in the summer months of June, July and August, was 20 per cent., as against a nil mortality in the colder months.

The review of general abdominal surgery occupies 260 pages and is very full of interesting work.

A book of this kind helps the busy surgeon to keep in touch with the most recent literature on surgery.

HANDBOOK OF OPERATIVE SURGERY.—By Sir William Ireland de C. Wheeler (Mod.), B.A., M.D. (Dub. Univ.), F.R.C.S.I., F.A.C.S. (Hon.). Fourth Edition. London: Baillière, Tindall & Cox, 1925. Pp. xvi plus 441, with 298 figs. Price, 15s. net.

THIS is a book of modest dimensions essentially for the use of students preparing for their final examinations.

There is an excellent chapter on local anaesthesia, and this is followed by short descriptions of the author's method of preparing a patient for operation and his routine treatment afterwards.

The descriptions of the various operations are good.

The illustrations are good, and the whole arrangement of the book is pleasing.

That a fourth edition has been reached is sufficient evidence that a place has been found for it in the student's ever increasing library, and there can be no doubt that it will prove extremely useful to those for whom it is intended.

A SYNOPSIS OF GYNÆCOLOGY.—By A. Gray, F.R.C.S., M.R.C.P. London: Edward Arnold & Co., 1925. Pp. 352. Price, 10s. 6d. net.

THE hand of the tutor can be seen all through Dr. Gray's "Synopsis of Gynaecology." Every point is arranged under headings with clearness and brevity. Important and common conditions such as fibroids of the uterus, carcinoma of the cervix and body, tubal gestation, and salpingitis are dealt with excellently. There are several attractive features.

We note with pleasure the chapter on the functions and dys-functions of endocrine glands in relation to gynaecology, and his statement regarding extract of thyroid gland. "It is the only ductless gland the extract of which supplies a true replacement for defective secretion. It is the only gland which used to be a duct gland discharging its secretion by the thyroglossal duct into the alimentary canal." This verdict may help to limit the sale of that machine-gun—erratic and uncertain—polyglandular extract.

Another very valuable chapter is that on forensic gynaecology, wherein the reader is shown clearly his duties and responsibilities to his patient and to the state and also the present state of the laws on the subject.

Our chief criticism is the size of the book. It seems a pity to include in a work, intended chiefly as a help to the already overburdened student, conditions which are described as being "all so rare as to be pathological curiosities" (vide, p. 198). There are three hundred and forty pages of highly condensed material and these do not include descriptions of operations.

If it were briefer it would be a more valuable aid to those studying for higher examinations and also as a means of refreshing the memory of teachers.

The book is well turned out and the printing excellent.

SURGICAL TREATMENT OF PULMONARY AND PLEURAL TUBERCULOSIS.—By J. GRAVESEN, M.D. (Copenhagen), with a foreword by S. Vere Pearson, M.D., M.R.C.P., Resident Physician, Mundesley Sanatorium. London: John Bale, Sons & Danielsson, Ltd., 1925. Pp. 155, with 87 illustrations (3 in colour). Price, 10s. 6d. net.

The work opens with a preface by the author followed by a "foreword" by Dr. Pearson. One pauses to enquire when this most exasperating manifestation of Saxonism will be finally consigned to the literary rubbish heap. "Foreword" may be Saxon, it certainly isn't English.

A better title for the work would perhaps have been "Collapse Therapy," as the surgical procedures dealt with in the book aim at securing collapse of the affected lung.

The author in his preface modestly disclaims any credit for originality and affirms that he is merely carrying out the work of his distinguished predecessor, the late Professor Christian Saugman.

The experiences and conclusions are exclusively based on clinical work accomplished at the Vejlebjerg Sanatorium, without reference to the work or figures of others. This has resulted in a gain to the work in clearness and brevity because in the author's words "the literature of the subject has become like an avalanche," and the author's object is to give a working plan of treatment.

The surgical procedures discussed are artificial pneumothorax, extra-pleural thoracoplasty, apicectomy, and phrenicotomy. Very full practical details are given in the section dealing with technique, and a well-timed warning as to the dangers of introducing air into the pulmonary circulation, with the almost inevitable sequel of death from air embolus in the brain or one of the branches of the coronary artery.

The last part of the book deals with the application of the foregoing measures to pleural tuberculosis combined with chemo-therapy.

In short, a very stimulating and suggestive work, and well worth perusal by all practitioners in this country whose work may bring them in contact with a class of case which is too often regarded as hopeless.

AN INTRODUCTION TO DERMATOLOGY.—By Sir Norman Walker. Eighth Edition. Edinburgh: W. Green & Son, Ltd., 1925. Pp. 373, with 92 plates and 80 illustrations. Obtainable from Messrs. Butterworth & Co. (India), Ltd., Post Box 251, Calcutta. Price, Rs. 15 net.

SKIN diseases to a very large percentage of medical practitioners are a matter of chronic irritation. The first symptoms of this irritation commence about a week before their final examinations when they make the discovery that they know nothing whatsoever about skin diseases, that a question on the subject is about due and that in any case they are likely to get something about 'skins' in their 'viva'; they therefore rush to the skin out-patient department only to have a whole afternoon wasted by a gentleman who has found a patient suffering from some very rare skin disease about the

ætiology of which he holds some very decided views, views which he shares with very few other people and certainly not with the examiner whom they are going to meet in a week's time. In desperation a recently passed friend is consulted; he is inclined to be cynical and optimistic, as most recently qualified men are, and replies, "You won't get a skin question this year; in any case you know that skin diseases are divided into two classes, those that react to zinc ointment locally and arsenic internally and those that don't; the first are cured by this treatment, the others are incurable. Well, I must be off, I hope you get through." This irritation, commencing thus in their early twenties lasts the greater part of their medical careers. They are told that Mrs. Jones' little boy's "eczema" which had resisted all their prescribing ingenuity has disappeared in 48 hours after the application of Jam Muk, that well advertised ointment; they are also told what Mrs. Jones thinks of doctors in general and of them in particular.

I do not claim to be able to prescribe a specific for this complaint but if your time as a student was too full to allow a regular attendance at the skin clinic then the purchase of a sound and well illustrated handbook on dermatology will certainly help to allay the irritation. For this purpose the book under review could hardly be improved upon. It is a short book (373 pages), written in a very pleasant style dealing concisely but at the same time completely with all the common skin diseases that one meets in everyday practice in England and, with some exceptions, in India. Above all it is very well illustrated; there are 92 full page plates, mostly coloured, and about the same number of text illustrations. We can thoroughly recommend the book both to the student and to the practitioner.

TUMOURS AND CANCERS.—By Hastings Gifford, F.R.C.S. London: Selwyn & Blount, Ltd., 1925. Pp. 703. Price, £2-2-0 net.

THIS is a biological study of tumours and malignant growths, replete with information and interest.

The work is divided into books or sections which deal with growth as instanced in plants and animals, with the development, origin, nature and natural history, cure and prevention of cancer.

The literature consulted in connection with the subjects discussed in the various sections is very extensive.

The general conclusions arrived at are of particular interest, especially those concerning the causation of cancer, wherein the author is inclined largely to incriminate the conditions of modern civilised life.

There is much to be said for the contention that retrograde influences are active "weakening the whole fabric of the most civilised nations."

The work is one which may be read with great interest by all concerned, either directly or indirectly, with the immense problem which we have to face in malignant disease.

POST-GRADUATE LECTURES. Vol. II. CANCER.—Edited by H. J. Paterson, C.B.E., F.R.C.S. London: John Bale, Sons & Danielsson, Ltd., 1925. Pp. 186, with 15 plates (43 figs.). Price, 12s. 6d. net.

THIS is a series of lectures dealing with the pathology and treatment of cancer occurring in various organs of the human body.

The first two lectures, one by Sir Thomas Horder and the other by Archibald Leitch, deal in a general way with the subject and do so in a very interesting manner.

Leitch gives it as his opinion, one strongly supported recently by Ewing, that frozen sections of pieces of tumours made rapidly during the course of an operation are of less value in diagnosis than a careful macroscopical examination of the tumour. With this conclusion there can be little dispute.

The remaining lectures, on cancer of the larynx by Sir St. Clair Thomson, carcinoma of the œsophagus by H. S. Souttar, cancer of the breast by Sampson Handley, cancer of the stomach by the Editor, cancer

of the uterus by Victor Bonney, cancer of the intestines by C. A. R. Nitch, malignant tumours of the kidney by R. H. J. Swan, of the bladder by Swift Joly, and of the rectum by W. E. Miles, are of great value and interest both in their pathological and clinical aspects.

As noted by the Editor, the lectures are given as delivered, in spite of the fact that there are occasional divergences of opinion. For example Leitch says that "it is unsafe to argue that the mammary gland in chronic mastitis is any more liable to become cancerous than the apparently normal breast," while Sampson Handley in his lecture remarks that "chronic mastitis is undoubtedly—and in my opinion beyond controversy—one of the predisposing causes of malignant disease."

The Editor leaves it to the reader to decide "what is truth," and in this case we concur with the surgeon.

These lectures, ably composed, and presented in a well produced and illustrated volume, are worth study by both pathologists and clinicians.

PHYSIOLOGY OF THE CENTRAL NERVOUS SYSTEM AND SPECIAL SENSES.—By N. J. Vazifdar, L.M. & S., F.C.S., F.C.P.S. Fourth Edition. Bombay: S. Govind & Co., 1925. Pp. 238, with 26 illustrations. Price, Rs. 4-8-0.

THE first edition of Dr. Vazifdar's "Physiology of the Central Nervous System and Special Senses" was published in 1911 and the fourth edition has now appeared.

The book is intended for students of physiology preparing for the medical degree examination. The fact that it is compiled from the best known text-books on the subject—Halliburton's "Handbook of Physiology," Howell's "Text-book of Physiology," Schäfer's "Essentials of Histology," Stewart's "Handbook of Physiology," Starling's "Principles of Human Physiology," Short's "New Physiology in Surgical and General Practice," etc., is sufficient guarantee of the quality of the contents. Being a resumé the book is useful to students and practitioners for revision and reference purposes. There are numerous diagrams and tabular statements which help not only in grasping the facts, but in remembering them. The popularity of the book is well deserved.

HEALTH AND PSYCHOLOGY OF THE CHILD.—Edited by Elizabeth Sloan Chesser, M.D. London: William Heinemann (Medical Books), Ltd., 1925. Pp. 302. Price, 7s. 6d. net.

MODERN psychology is prolific nowadays in new publications. This book, however, is a new departure in that it appeals to those who have the physical and mental welfare of the child at heart. To parents, teachers, members of the medical profession and all religious instructors it is a highly commendable book, as its several chapters have all the stamp of authority, being written by men and women whose names recall to one's mind the subject with which they deal. Tredgold devotes a chapter on delinquency in children; Leonard Williams on the endocrine glands and vitamins; Lady Baden-Powell on the value of training; Percy Hall on the value of sunlight on children; Viscountess Erleigh on mothercraft, etc. The book is "all-embracing" in its handling of the subject, and as a perusal of its contents will indicate, the subject is approached from many standpoints.

In a chapter on "the physical aspects of adolescence" by Sir Bruce Bruce-Porter, the following occurs:—"There is no doubt the nations of the world who are the most powerful in physique and peaceful in mind are the non-meat eating races and so in the animal world. The animals that do the heavy work are cereal feeders, while the nervous nations and nervous animals are the carnivorous." I believe many distinguished medical men, such as Lieut.-Col. McCay, Lieut.-Col. McCarrison, I.M.S., and Professor Mellanby of Sheffield would dispute such a statement.

Again he states "..... even cancer may be traced to this chronic poisoning (neglect of the bowel)".

This very probable hypothesis regarding the cause of cancer cannot, I believe, be accepted as a scientific fact.

As an introduction to the study of mental phenomena by analytical or psycho-analytical means the study of the child mind is undoubtedly the simplest. This book is therefore commended to all those who have a baby or children to experiment with, and a highly interesting experiment it is bound to be if the thoughts expressed and the principles laid down are taken to heart.

THE CEREBRO-SPINAL FLUID IN CLINICAL DIAGNOSIS.—By J. Godwin Greenfield, M.D., B.Sc., M.R.C.P. and E. A. Carmichael, M.B., Ch.B. London: Macmillan & Co., Ltd., 1925. Pp. 272. Price, 12s. net.

THIS is a comprehensive and well arranged work dealing with the characters, normal and abnormal, of the cerebro-spinal fluid, and with its anatomical and physiological relationships.

There are also sections detailing the alterations encountered in certain diseases, and the technique employed in various methods of examination.

The authors write with the authority of their special experience in the National Hospital for the Paralyzed and Epileptic in London and have produced a valuable work of reference for physicians and laboratory workers.

A good list of references to books and special articles is included.

"BILHARZIA: A PAPER FOR THE PRACTITIONER."—By F. Gordon Cawston, M.D. (Cantab.). London: John Bale, Sons & Danielsson, Ltd., 1925. Pp. 20. Price, 2s. 6d. net.

THIS little booklet, which is a reprint from a paper in the *Journal of Tropical Medicine and Hygiene*, gives a brief account of Bilharzia disease as it occurs in South Africa, laying particular emphasis on the points which are of interest to the general practitioner.

After a few preliminary pages on the occurrence of the disease, the method of infection and the life cycle of the parasite, the author briefly describes the principal symptoms and pathological conditions associated with the disease, and then devotes most of the remaining half of the article to treatment. Only one course of treatment is described, and the details of the technique are made almost childishly simple, so that any practitioner, however inexperienced, could hardly make a mistake if he followed directions. If one is to judge the technical ability of the practitioners for whom the book is written by the completeness of these instructions then it would seem that the short paragraph on the complement-fixation test which follows is so inadequate as to be practically worthless. For these readers, also, it seems that a more thorough description of the ova and method of recognising them, even at the expense of some of the description of the cercariae, would have been useful.

PREPARATION OF SCIENTIFIC AND TECHNICAL PAPERS.—By Sam F. Trelease and Emma Sarepta Yule. Baltimore: Williams & Wilkins Co., 1925. English Agents: Messrs. Baillière, Tindall & Cox, London. Pp. 113. Price, 7s. 6d. net.

THIS book was written for the benefit of the senior student and the scientist who has had little practice in putting the result of his work on paper. If it were compulsory for every contributor to a scientific journal to read a book such as the one under review, much of the editors' time would be saved. The book was not written particularly for the medical man but the advice given is almost all applicable to papers on medical subjects. An attempt is made to show the reader how he should put his ideas on paper, how he should arrange them in the form of a balanced paper and how he should rearrange his paper and correct his mistakes.

SEPT., 1925.]

Valuable information on the use and abuse of capital letters and italics is given. There is a section on the methods of literature citations, or references; this section occupies nearly a quarter of the whole book and goes into the matter very thoroughly. Three different methods are given. It is not very apparent what difference exists between the second and third method and the methods are not criticised. The third method is, I think, the one which is generally accepted as being the most practical. A list of abbreviations for well-known journals is given. This list is very incomplete. I feel that it would have been better to have made the list more complete, even if this meant a considerable increase in the size of the volume, or, as an alternative, a short discussion on the principles which govern these abbreviations would have been more useful than an incomplete list. The section on proof reading is disappointing; the suggestion that proofs should be read through three times being compared line by line with the original is not very helpful. Mistakes are much more likely to be noticed if the paper is read through slowly and intelligently, reference only being made to the original in the case of figures. The line-for-line method might be followed for the first reading only, especially when the proof reader is unfamiliar with the subject-matter of the paper. A few useful hints about the common tricks of compositors would have been useful; for example, if a letter is missing from a word, there is usually a very fair chance that the missing letter will be found in an inappropriate place in the next line.

There is much valuable information in the book but there is much that has been left out. I cannot help feeling that we have not quite received our money's worth.

ELEMENTARY ANATOMY AND PHYSIOLOGY FOR NURSES.—By H. Clifford Barclay, M.D., Ch.B., M.R.C.S., L.R.C.P., F.R.C.S.E. Third Edition. London: Baillière, Tindall & Cox, 1924. Pp. x plus 411, with 49 figs. in the text. Price, 12s. net.

This book is an honest attempt to make anatomy and physiology interesting and intelligible for nurses during their training. We cannot but feel, however, that the text is too discursive, and that the chapters on embryology, comparative anatomy, psychology, and the emotions are more than the average nurse can be expected to assimilate.

CHININUM.—Presented by Bureau tot Bevoordering van het Klinie Gebruik, 48 De Wittenkade, Amsterdam.

This little book, designed to popularise the use of quinine in various conditions apart from malaria, is a collection of articles by various authors on the administration and value of quinine in certain diseases.

It also contains a series of 24 heliotypes on cinchona culture in Java.

In an early chapter the action of quinine is lucidly described by Professor H. Kionka, of the University of Jena. This section is well worth reading by the pharmacologist as well as the practising physician.

It should be a work of great interest to the student and practitioner of medicine as it brings home to one that the medicinal uses of quinine are not confined to its use in malaria.

AN AFRICAN HOLIDAY.—By Richard L. Sutton, M.D., LL.D. St. Louis: The C. V. Mosby Co., 1924. Pp. 180, with 102 illustrations. Price, \$2.25.

This little book is a fascinating story of the author's experiences in Africa shooting big game. It is clearly and simply written and fully illustrated with actual photographs. It will appeal to all sportsmen and lovers of Nature.

Annual Reports.

ANNUAL REPORT ON THE JAIPUR MEDICAL INSTITUTIONS FOR 1923. BY DALJANG SINGH KHANKA, M.B., RAI BAHADUR. SUPERINTENDENT OF DISPENSARIES AND VACCINATION, JAIPUR.

THERE were 2,982 births as against 4,122 deaths in Jaipur city during the year, but the actual death rate, 34.28 per mille, is very similar to that of most Indian towns. More than half the mortality occurred among children of less than five years of age. Small-pox was mildly epidemic during the year and caused 106 deaths, December being the month in which the incidence was greatest. From September to December Jaipur was stricken with dengue, and five emergency sub-assistant surgeons were specially deputed to go round their circles morning and evening, treating cases and issuing instructions for anti-mosquito measures. Plague, influenza and cholera were fortunately absent during the year. "The sanitary condition of the city was in the same deplorable state as in previous years" writes Dr. Khanka; "so nothing more need be said about it"; he hopes, however, that the newly appointed Municipal Board will take steps to deal with it. An interesting feature of the report is that 60 mad dogs, captured inside the city during the year, were taken far away into the jungles and there liberated. The number of vaccinations carried out shewed a satisfactory increase, some 23 per mille of the population being vaccinated annually.

Twenty-nine hospitals and dispensaries were at work during the year and treated 2,31,824 out-patients and 5,403 in-patients. At the Mayo Hospital a large volume of surgical work was carried out during the year, eye work and operations for vesical calculus being especially prominent. Litholapaxy was carried out on 56 patients with only 1 death, and an analysis is given of the results. The duration of symptoms varied from 1 day to 3 years, the average time for the operation was some 20 minutes, and the largest stone dealt with weighed 1,230 grains. The average stay of these patients in hospital was only 4.69 days.

PASTEUR INSTITUTE OF SOUTHERN INDIA, COONOR. ANNUAL REPORT FOR THE YEAR 1923-24. BY LIEUTENANT-COLONEL J. W. CORNWALL, M.A., M.D., I.M.S. MADRAS: SUPERINTENDENT, GOVT. PRESS. 1924.

THE most striking feature in this report is the tremendous decrease in the number of patients treated at Coonoor, owing to the extended issue of the anti-rabic vaccine to government headquarter hospitals. Only 1,354 patients were treated at Coonoor, as compared with 3,375 for the previous year; whilst the numbers treated outside Coonoor rose for the same period from 1,248 to 3,692. The total number of patients treated with the Coonoor vaccine during the year, on adding up the above figures, shews the usual annual increase, 5,046 in 1923-24, as against 4,623 in 1922-23.

The vaccine is issued from Coonoor in sealed ampoules, and it is of some interest to compare the results of institutional treatment at Coonoor with those of treatment elsewhere. It had been anticipated that a considerable number of the patients treated at hospitals would fail to complete the course of treatment, but this has proved not to be the case; only 3.5 per cent. failed to attend daily for the complete course of treatment. On the other hand, it has proved exceedingly difficult to get in the desired reports and returns; information as to results could not be obtained with regard to no less than 40 per cent. of patients treated at hospitals. As a result the statistics for the Institute are not strictly comparable with those for patients treated elsewhere: at the former the total hydrophobia incidence was 0.29 per cent., among the 60 per cent. of those treated outside about

whom information is available, the total hydrophobia incidence was 0.84 per cent. Inasmuch as the total hydrophobia incidence at Coonoor for the years 1907 to 1924 works out at 0.97 per cent., however, the latter figure is not bad.

Turning to the comparative mortality amongst the treated and untreated respectively, Tables IV and V continue similar information given in previous years. In Table IV the death-rate from hydrophobia among 829 treated patients was 2.8 per cent.: as compared with a rate of 6.3, among 1,388 persons bitten by the same animals, but not treated. In Table V it is certain that the biting animal was both rabid and infective at the time of biting as shewn by the occurrence of at least one death from hydrophobia in each group of persons bitten. Here the mortality rate for the untreated works out a 35 per cent. "The figures shew very clearly" claims Colonel Cornwall, "that the risk of dying from hydrophobia, if bitten by a rabid animal which is really infective, is not less than 1 in 3.....as far as our information goes, this risk may be diminished by one-half by the anti-rabic treatment."

In Part III of the report, in view of the fact that in future the Institute is likely to become more and more of a vaccine distributing centre, and less and less of a treatment centre, an analysis is given of the Institute reports from 1907 to 1924. This provides a very useful summary of the facts. European patients contain so very large an element of those not in any way at risk that only 4 "failures of treatment" are recorded out of 2,648 such patients treated. Delay is clearly shewn to increase the risk, but 80 per cent. of patients arrive within 10 days of having been bitten. Rabies appears to be equally prevalent among dogs in Madras Presidency all the year round, but the number of persons bitten is slightly greater in the hot weather than in the cold,—possibly owing to the custom of sleeping out of doors in the hot weather. The percentages of deaths work out at 7.7 per cent. for persons bitten on the face, 1.0 per cent. for those bitten elsewhere on naked skin, and only 0.27 per cent. for those bitten through clothing. The second category of cases, however, constitutes 82.2 per cent. of the deaths which occurred. Of 30,253 patients treated between 1907 and 1924 more than a half, or 17,606 came from the Madras Presidency, and 3,460 from Mysore. Dog-bites totalled 95.7 per cent. as against only 2.7 per cent. of jackal-bitten cases. An interesting case recorded in the report of a male patient, aged 6, who developed hydrophobia no less than 411 days after being bitten by a rabid dog, and 398 days after completing treatment: the bites consisted of 4 tooth marks on the left buttock and small of the back.

Financially the net receipts for the year amounted to Rs. 73,689, and expenditure to Rs. 46,977.

GOVERNMENT GENERAL HOSPITAL, MADRAS.
ANNUAL REPORT FOR THE YEAR 1923.
SUPERINTENDENT, GOVERNMENT PRESS,
1924. PRICE RS. 6.

As is customary, this report is divided into two sections:—(a) administration report; and (b) professional reports by the staff,—the latter of which are full of interest. The accommodation available during the year was 528 beds, and the daily average sick treated 503. Out-patients during the year numbered 60,174 and in-patients 9,444. The chief causes of death among the latter were in order—diseases of the digestive system, 80 deaths; pneumonia, 64; injuries, 45; diseases of the circulatory system, 39; phthisis, 38; and other respiratory diseases, 22. The figures of percentage of deaths among patients admitted for different diseases are of interest, as reflecting conditions in a large general Indian hospital; some of the case mortalities recorded being—28 per cent. for pneumonia, 24 per cent. for diseases of the circulatory system, 20 per cent. for phthisis, 14 per cent. for enteric fever, 12.6 per cent. for kala-azar, 8.8 per cent. for dysentery, and 7.7 per cent. for liver abscess. (The figures are for Asiatic patients only).

Malaria shewed an increased prevalence in Madras during the year,—7,092 patients treated as against 5,850 in the previous year. The total number of operations performed was 2,461; whilst 283 medical students and 79 nursing probationers were taught.

The average daily cost of in-patients worked out at Rs. 0-9-3½ per Indian, and Rs. 0-15-10½ per European patient. Receipts and expenditure totalled Rs. 7,51,338, the chief items of the latter being miscellaneous charges, Rs. 1,59,431, and diets, Rs. 1,33,121.

Turning to the professional side of the report, Major G. E. Malcolmson, I.M.S., was in charge of the First Physician's wards. He notes that in 20 per cent. of the amoebic dysentery cases, malarial parasites were found in the blood, often without accompanying rise of temperature and usually of species *P. vivax*. In most of these cases, emetine stopped the blood and mucus, but an obstinate enteritis persisted, which in some instances yielded to quinine injections. The point is raised as to the association, if any, between the malaria and the dysentery. In some cases of quartan malaria parenchymatous nephritis was noticed. Interesting cases recorded are two cases of kala-azar with death from extensive hæmorrhage, and another case of kala-azar which died of perforation of an amoebic ulcer of the hepatic flexure of the colon, the only symptoms from which were a slight looseness of the bowels. At autopsy extensive ulceration of the colon was found. Ataxic paraplegia is noted as present in a case of benign tertian malaria; 10 cases of diabetes treated with insulin shewed rapid improvement; whilst brilliant green proved a failure in the treatment of kala-azar.

Major J. M. Skinner, I.M.S., was acting Second Physician. He records an interesting case of pneumococcal arthritis of both ankle joints with acute onset, in a boy of 16, two days after the crisis of lobar pneumonia. Salicylates had no effect at all in relieving the pain, but immediate recovery followed after injection of polyvalent anti-pneumococcal serum. Another interesting case was one of extensive pericardial effusion. The onset was gradual, with no history of rheumatism, and the patient remained at work until within two days of her admission to hospital. The cardiac dullness extended to the left mid-axillary line and two inches to the right of the sternum. Paracentesis removed 8 ozs. of blood-stained fluid.

Major W. L. Forsyth, I.M.S., Third Physician, notes on the large number of cases of asthma seen. Adrenalin injections gave relief in some 90 per cent. of cases, but belladonna, stramonium and the anti-spasmodic group of drugs proved useless. "The treatment of malaria remains the same,—intravenous quinine plus quinine by the mouth with free administration of alkalis to bring the urine to an alkaline pH." In valvular heart lesions with much oedema and ascites, large doses of the infusion of digitalis give better results than does the tincture. Many of the female patients admitted shew extreme anaemia associated with acute pyorrhœa and the presence of a hæmolytic streptococcus in the gums. The need for education in schools, on dental matters, is not half realised in India.

Dr. M. R. Guruswami, Fourth Physician, records a case of a patient aged 38, admitted with acute dilatation of the heart and orthopnoea. Venesection and other measures relieved the condition, which, however recurred. The periodicity of the attacks aroused suspicion, the blood was examined and malignant tertian parasites found. The patient improved considerably on quinine treatment. A second interesting case was one of mixed tenia infections, the patient suffering from intense neuro-retinitis and dying in convulsions. Post-mortem examination shewed one *Tenia saginata* in the gut, and numerous cysts of *Cysticercus cellulosæ* throughout the cerebrum, and especially in the grey matter. Ten cases of broncho-pneumonia were associated with intense ascaris infections,—one of them passing 350 worms, under treatment; the lung condition

SEPT., 1925.]

improved in all, on anthelmintic treatment. Another interesting case was one shewing signs of complete consolidation of the left lung, but with a positive Wassermann reaction; the condition simulated phthisis, but there were no signs of cavitation, and the case cleared up completely on anti-syphilitic treatment.

The very interesting report of the First Surgeon, Lieutenant-Colonel E. W. C. Bradfield, I.M.S., has already been published in our columns: (*Indian Medical Gazette*, October 1924, p. 515). Lieutenant-Colonel R. B. B. Foster, I.M.S., Second Surgeon records 672 operations during the year, with a mortality of 8.9 per cent.: this, however, includes 16 cases admitted in a moribund state. Interesting cases were (1) A case of fracture of the atlas, with complete paralysis and some wasting of the muscles of the extremities, but without sensory disturbance. Complete recovery of function ensued, but with slight angular deformity and rigidity of the neck. (2) Two cases of cystic goitre about the size of a coconut each; complete removal of the gland was not followed by any evidence of thyroid disturbance. (3) A patient from whom a thyroid carcinoma had been removed five years previously: re-admitted with metastases in the cervical and axillary glands and vertebrae, with spastic paraplegia. (4) A case of lympho-sarcoma of the duodeno-jejunal flexure, cured of symptoms by posterior gastro-enterostomy.

Major K. G. Pandalai, Third Surgeon, records the successful use of spinal anaesthesia in patients who were in a poor state, with no trained anaesthetist available; amongst other operations conducted under spinal anaesthesia were gastro-enterostomy, partial gastrectomy, excision of a tubercular caecum, and hernias. In 80 per cent. of the cases of gastric or duodenal ulcer, there was no difficulty in diagnosis, but in the others where this disease was suspected such diverse conditions as chronic appendicitis, visceroposis, hepatic cirrhosis and tubercular peritonitis were found. In 9 cases with symptoms typical of ulcer, no abdominal lesion could be found: the abdomen was closed, but the patients returned later with the same symptoms, and posterior gastro-enterostomy cured the symptoms; hyperchlorhydria was the probable cause of them. The degree of mobility of the ascending colon varies very widely, claims Major Pandalai, and he has given up fixation operations. Sixteen cases of liver abscess were treated by aspiration plus emetine with complete success, and 3 cases of elephantiasis of the leg by the Kondoleon operation with good results. In the treatment of ventral hernias, the abdominal musculature is often found to be weak and atrophied; the use of filigree implantation is here useful. In a case of aneurism of the innominate artery and arch of the aorta, the third part of the axillary artery and the common carotid immediately below the omohyoid were ligated at the same sitting; the result was completely successful. A growth of a jet black colour, $1\frac{1}{2}$ in. \times $\frac{3}{4}$ in. at the outer canthus of the left eye, involving both lids, was found to be a melano-endothelioma. Four cases of suppuration in the antrum of Highmore were admitted,—all due to retained stumps after tooth extraction. One of these developed abscess of the lung after operation, but ultimately recovered. In an infant one year old, a large swelling was found filling the entire pelvis. On operation the swelling proved to be a congeries of thick-walled, cystic spaces containing mucoid fluid, the upper end of the swelling extending to the level of the kidneys, its position being retro-peritoneal and in the mid line in front of the vertebral column. The sacrum and coccyx were practically absent. The cysts were reported on by the pathologist to be of ependymal origin.

In the out-patient department, Major Paton complains of the very urgent need for improving the emergency operation theatre, and also pleads for the commencement of a skin out-patient clinic. During the year 797 patients attended for anti-rabic treatment, but only 399 of them completed the 14 days' course of

injections. The growth of the work in the x-ray Institute under Captain T. W. Barnard is shewn by 17,778 exposures or treatments in 1923 as against 11,757 in 1922 and 2,531 in 1919. The results in x-ray treatment of cancer are encouraging and special apparatus is being imported for this. An exhibit was accepted by the Royal Photographic Society of Great Britain for their 68th annual exhibition in London. In the Dental Department 4,566 patients were treated during the year.

As will be seen, the report covers a wide area of professional interest.

ANNUAL REPORT ON THE CIVIL HOSPITALS AND DISPENSARIES IN THE MADRAS PRESIDENCY FOR THE YEAR 1923. MADRAS: SUPERINTENDENT, GOVERNMENT PRESS, 1924. PRICE, RS. 2-6-0.

At the close of the year 1922 there were 758 medical institutions of all classes in the Presidency. Eighteen new dispensaries were opened and eight closed, leaving 768 in working order on the last day of the year 1923. Of the newly opened dispensaries three were State-public, twelve Local Fund, and three private non-aided institutions. Seven dispensaries out of the eight closed during the year were Local Fund institutions and one was a private non-aided dispensary.

Medical progress in many parts of the presidency was much hampered by the straitened circumstances of Provincial finances. It is hoped that a large number of new medical institutions will be established when funds become available. The question of opening more hospitals and dispensaries in each district in places at which their need is most felt, thus securing adequate medical aid to the people of the presidency, is at present engaging the attention of the Government.

The patients treated in in-door departments of the hospitals and dispensaries of this presidency numbered 133,910 in 1923 against 131,510 for the previous year.

To the improved and special arrangements calculated to secure greater attention and comfort to all patients must be attributed the rise in the number of in-patients in almost all medical institutions. Of the in-patients treated, 83,178 were cured, 23,870 relieved and 16,686 discharged otherwise against 80,751, 24,360 and 15,841, respectively, in 1922.

There were 6,012 deaths during the year and the death-rate was 4.49 as compared with 4.67 in 1922. The death-rate, it is noted, is greater in the city State institutions than in the mofussil ones, as the former admit many more accident and serious cases than the latter.

Consequent on the increase of in-patients, the daily average attendance, which was 5,812.31 in 1922 rose to 6,048.30 in 1923.

The number of beds available (excluding 171 beds common to both Europeans and non-Europeans in the Government General Hospital, Madras) was 7,907 (4,479 for men and 3,428 for women) as against 7,859 (4,478 for men and 3,381 for women) in 1922. The increase in the number of beds for women speaks well of the popularity of the institutions and of the lady doctors in charge.

Altogether 8,220,258 and 8,098,588 patients sought outdoor relief at the hospitals and dispensaries in 1923 and 1922, respectively. The excess over the previous year's figures is 121,670. The out-door work of the institutions is progressing yearly. The combined total of in and out-door patients was 8,354,168 in 1923 as compared with 8,230,098 in 1922.

The steady rise in the number of patients treated was mainly due to the increasing appreciation of western methods of treatment and the popularity of the medical officers and subordinates.

As usual malaria contributed a very large number of patients. Diseases of the skin and ear were responsible for 979,714 and 559,215, respectively, of the patients treated. Affections of the eye are among the most common ailments and the attendance on this account has shown a rapid increase.

366,661 operations were performed on 356,721 patients as compared with 337,127 operations on 327,660 patients in 1922, showing an increase of 29,534 operations. The statements received from District Medical Officers and Superintendents of other institutions show a marked increase in the number of operations performed at the various hospitals in the presidency. Instruments and appliances to meet the requirements were supplied to all hospitals and dispensaries. 26,501 operations were returned as really "major" against 24,350 in 1922. The death-rate among the patients operated on was only 2.4 per cent. The excess in the number of operations over that of the previous year and the low death-rate shows the increased confidence of the public in the surgeons and the greater care devoted by them to the patients operated on.

The year opened with a cash balance of Rs. 17,215 against Rs. 13,040 in the previous year. Government contributions during the year amounted to Rs. 29,11,709. Local Boards and the municipalities contributed Rs. 25,98,639, or nearly 44.1 per cent. of the receipts. The contributions from Government show an increase proportionate to the growth in expenditure. The total expenditure during the year amounted to Rs. 58,91,569.

Hookworm Disease.—During the year 20,790 persons were examined for hookworm infection. Of these, 16,563 persons or 79.70 per cent. were found to harbour the parasites in greater or smaller numbers. Ninety-four per cent. of persons examined for all intestinal parasites harboured some kind of intestinal parasite or other. The total number of treatments administered during the year in various localities was 93,469. The educational side of the campaign is notable inasmuch as 3,034 lectures with lantern slides were delivered in various vernaculars to audiences aggregating 274,000. The source of infection of hookworm and its remedy were well impressed on the audiences by the lectures and by free distribution of pamphlets and leaflets and the publication of a series of articles on the subject in the local newspapers. The Director is to be congratulated on the success of the campaign during the year.

Small-pox.—During 1923 the total treated was 1,702 with 192 deaths against 2,395 with 393 deaths in 1922.

The total cadre of appointments for Indian Medical Service officers in the Madras Civil Medical Department (including jail and bacteriological appointments and the leave reserve) was fixed at 50. The leave reserve for Indian Medical Service officers was increased from 20 to 27½ per cent. Eleven appointments hitherto reserved for Indian Medical Service officers were thrown open to members of the Madras Medical Service. In accordance with the recommendations of the Public Health Retrenchment Committee the leave reserve for civil assistant surgeons and sub-assistant surgeons was reduced from 15 and 25 per cent., respectively, to 10 per cent. in both cases and the plague reserve for sub-assistant surgeons was abolished. As the pay of the officers of the Madras Medical Service was raised from 1st April 1920, the minimum as well as the maximum having been increased a hundred per cent., Government abolished the charge allowance of Rs. 30 per mensem drawn by civil assistant surgeons holding sanctioned appointments on the ground that there was no justification for the retention of such an allowance. The pay of the sub-assistant surgeons having been revised several times since 1894, the initial as well as the maximum pay having been doubled since 1916, the Government considered that there was little justification for the retention of the free quarters or house-rent allowance in lieu thereof in their case. Accordingly, orders were passed withdrawing the concession from sub-assistant surgeons.

ANNUAL REPORT OF THE DIRECTOR OF PUBLIC HEALTH, MADRAS, FOR THE YEAR 1923. BY DR. K. T. MATTHEW, L.R.C.P., L.R.C.S. (EDIN.), D. HY. (DUR.), D.P.H., (CANTAB.), MADRAS: SUPERINTENDENT, GOVERNMENT PRESS, 1924. PRICE 14 ANNAS.

THE year under review saw the formal establishment of a complete self-contained public health staff working under the district boards throughout the Presidency. The lines on which the campaign against disease and death was to be conducted had been laid down in advance and the campaign was started in April 1923 by a small but well-trained and well-disciplined corps of health officers under the generalship of the Director of Public Health and his staff of assistants. The period of nine months during which the campaign was carried on in the year under review is too brief to admit of any decisive victory in the almost never-ending war between man and the microbe; nevertheless in more than one field notable success has attended the efforts of the public health staff, helped by hearty co-operation on the part of local authorities and the public generally. The success achieved was particularly marked in the campaign against cholera and relapsing fever, and specially good work was done in the districts of Coimbatore, Tanjore, Trichinopoly, Kistna and Madura. A few salient details relating to the more important disease are given below.

Cholera.—Deaths from cholera showed a considerable decrease, the number registered during the year being 5,169 (0.1 per mille) against 16,502 (0.4 per mille) in 1922 and the quinquennial average rate of 1.4 per mille. This figure is the lowest on record though no district was entirely free, and the delay of the village officers in reporting outbreaks of the epidemic, of which there were very many instances, seriously handicapped the efforts of the health staff. Excellent preventive work in the shape of epidemiological investigation was done in the districts of Cuddapah, Coimbatore, North Arcot and Ganjam. The marked decline in cholera mortality in the Ganjam district may reasonably be attributed to such preventive work, coupled with special precautionary measures for guarding probable sources of infection. Excellent work was also done in South Kanara where, as the result of special care taken by the Health Officer and his staff, the villages seriously affected by floods escaped from epidemics of every kind.

Small-pox.—The number of deaths from small-pox rose from 22,801 to 24,434, the death-rate being very high in South Arcot and Malabar. The fact that about 35 per cent. of the total mortality from small-pox occurred among children under one year and another 35 per cent. occurred among children under 10 years clearly demonstrates the urgent need for more vigorous action on the part of local bodies and their health staff in respect of primary vaccination. It is melancholy to reflect that a disease like small-pox which has been almost entirely eliminated in most civilised countries for very many years by the adoption of simple, seasonable and sure preventive measures should in this country continue even in the 20th century to kill over 24,000 human beings and leave marks of its ravages on many more. It would indeed appear that ignorance and prejudice are most serious obstacles to the advancement of public health, especially when they are not confined entirely to the illiterate masses who know no better but are to be found even among the higher strata of the community. Educational propaganda to produce its real effect cannot therefore be limited in scope to the former class but must be made to reach the latter also.

Plague.—The number of deaths from plague rose from 9,193 in 1922 to 12,110 in 1923. Sixteen districts were affected, but 96 per cent. of the total mortality from the disease occurred in four districts, viz., Madura, Coimbatore, Salem and Bellary. It is observed that the largest number of inoculations was also

made in these districts. Inoculation does not, however, cut at the root cause of the outbreak of plague. Plague is a disease of rats and unless on the one hand the importance of rat destruction and of the construction of rat-proof godowns and houses on the other is fully recognized and permanent preventive measures are adopted no radical improvement can be reasonably expected in the existing state of things.

Relapsing fever.—Relapsing fever was prevalent in ten districts. Though there were about 400 deaths in the first quarter of the year in the Tanjore district from relapsing fever, the epidemic was, by the end of March, effectually eradicated from the district as a result of prompt and vigorous action on the part of the health staff. In the Trichinopoly district, where the epidemic continued till the middle of 1923, effective preventive measures were taken by the district health staff in the shape of propaganda and an intensive de-lousing campaign. The timely action of the district health staff probably saved the Bellary district from the danger of an epidemic of relapsing fever. The success which attended the campaign against relapsing fever everywhere is a striking example of the inestimable advantage derived from a well-trained and properly equipped public health staff, an advantage which some local bodies even in urban areas do not appear always to realize.

Hookworm disease.—The anti-hookworm campaign was conducted on a large scale during the year. The North Arcot district was selected for an intensive educational campaign, the object being to carry the treatment to the very doors of the people and to familiarize them with the commoner aspects of the disease and the methods of bringing it under control. Nearly 3,000 lectures were delivered to audiences aggregating 265,000 persons during the year; 93,469 treatments were administered. Of 20,790 persons examined at random the percentage of infection with hookworm was 79.7.

Registration of vital statistics.—In spite of the efforts of the newly appointed district health staff, registration continued to be defective. A noteworthy feature was that registration was more unsatisfactory in several areas where it is compulsory, than in areas to which compulsion has not been extended, a reminder to public authorities that compulsion is neither the only remedy nor a sure remedy. The importance of accurate vital statistics must be brought home not only to the registering officers but to the people also, before any real improvement can take place in registration work. Errors in compilation are likely to be reduced when the work of compilation is transferred to the District Health Officers. The fact that as many as 62,214 unregistered births were detected by the district health staff and that there were several instances of deaths from cholera registered as deaths from fevers illustrates the defective and inaccurate character of the work performed by registering officers. There was, however, appreciable improvement in the registration work in rural towns.

Birth-rate.—The birth-rate exceeded the death-rate in every district. Only the Chittoor and Nellore districts showed a decrease of 8.8 and 1.2 per mille, respectively, on the previous year's rates. The recorded birth-rate for the Presidency was 33.1 against the estimated average rate of 42.5. The birth-rate for the year is greater than the decennial average for the ten years ending 1922 by 2.9 per mille.

Death-rate.—With the exception of Cuntur, Kistna and South Arcot, all the districts showed a decreased death-rate when compared with the decennial average. All districts except six showed, however, an increase in the death-rate as compared with 1922, the increase being most marked in Cuntur, South Arcot. The death-rate during the year was 173.7 per mille of registered births against 166.4 in 1922 and 182.3 the quinquennial average. The death-rates in municipalities, however, shewed a decline. The general impression created

by the mortality figures is a saddening one, especially the figures of infant mortality. The death-rate is a reliable index of the general state of public health; as the general health mounts higher the death-rate sinks lower and vice versa. This is so because conditions affecting health, though they may not prevent or cause death in the individual, may nevertheless produce a marked variation in the general death-rate. In a total mortality of 908,825 during the year there were no less than 235,969 deaths of infants under 1 year, and 134,615 deaths of children between 1 year and 4 years. No one who ponders seriously over these tragic facts can avoid coming to the conclusion that the welfare of children who cannot look after themselves has failed to receive the care and attention rightly due to it from either their parents and guardians or the local authorities who are primarily responsible for public health administration.

Maternity and child welfare.—The total number of deaths registered under maternal causes in districts including municipalities was 2,892. This figure does not, however, represent the actual mortality which cannot be much below 25,000. The high rate of maternal and infantile mortality must be attributed mainly to the ignorance of the people and partly to the lack of efficient medical relief in rural tracts. A gradual elimination of the latter cause may be expected when the scheme which the Government have under consideration for the extension of medical relief in rural areas is brought into effect. The cordial response made by the people in rural areas to the health and baby welfare movement on the one hand and the gratifying success achieved in this field in the presidency town on the other, indicate that ceaseless propaganda in the villages and the organization of child welfare centres in charge of lady health visitors in urban areas are the two main lines on which public and private efforts to improve maternal and child welfare should proceed in future.

Propaganda.—The great value of propaganda work as a preventive measure was illustrated at a lecture on plague delivered during the National Health and Baby Week at Ranipettai. One of the audience, on hearing that plague infection was carried through rats, at once gave information that there were rat falls in the town, and this led to the discovery of the disease and the taking of prompt measures in time with excellent results.

Owing to the praiseworthy labours of the Madras Health Council and the efforts of the district health staff, health propaganda received considerable attention during the year. Lectures were delivered to large audiences, and posters and pamphlets distributed at the close of the lectures, and demonstration made with the aid of magic lanterns. Until the health staff are sufficiently equipped with magic lanterns and accessories, propaganda work will continue to suffer a serious handicap.

Fairs and festivals.—The arrangements made were, on the whole, adequate and satisfactory. It is also gratifying to note that there was no outbreak of any epidemic at any of the festival centres, the arrangements for which were supervised by the district health staff.

No new scheme of water-supply or drainage was brought into operation during the year. On the recommendation of the Retrenchment Committee, the Government abolished three posts of Assistant Director of Public Health and re-distributed the duties of the remaining three on a functional basis with headquarters at Madras. This measure of economy has not involved any loss of efficiency but has, on the other hand, brought about better co-ordination of the work of the District Health Officers in the various branches of public health administration. A great deal has been attempted, a good deal done, and a great more remains to be done. Public health is not a field in which an early harvest can ordinarily be expected. The acting Director, Dr. Matthew, is to be congratulated on his

successful administration of the department during the absence of the permanent Director on leave.

ANNUAL REPORT OF THE HOSPITALS AND DISPENSARIES, BIHAR AND ORISSA, FOR THE YEAR 1923. BY COLONEL H. AINSWORTH, M.B., F.R.C.S., I.M.S. PATNA: SUPERINTENDENT, GOVERNMENT PRINTING, BIHAR AND ORISSA, 1924. PRICE RS. 4.

THERE were 485 hospitals and dispensaries open on the 1st January and 546 on the 31st December 1923, an increase of 61 against 31 in 1922. Seventy-seven new dispensaries were opened during the year, 62 by district boards, 13 by railway companies and 2 by private bodies. Sixteen dispensaries were closed during the year. Of these, 7 were maintained by local bodies and 5 by private bodies; 3 were railway hospitals and 1 a Public Works Department (Irrigation) dispensary.

The total number of patients treated at the State-public, Local Fund and private-aided dispensaries was 3,586,552 against 3,136,281 in 1922 or an increase of 450,271 which is shared by all classes of dispensaries except travelling dispensaries. The fall in attendance at the travelling dispensaries in 1923 was due to the closure of some of them. When new dispensaries were opened in certain districts, the travelling dispensaries were abolished.

The year was a healthy one. The death-rate was 25.0 per mille compared with 24.1 in the preceding year. This slight increase was probably due to malaria and plague which were prevalent in certain districts.

The total number of deaths from cholera decreased from 26,805 to 8,198. 3,967 cases were treated in hospital compared with 4,698 in the previous year. These figures appear to shew that there is an increasing tendency on the part of the people to bring these patients to hospitals for treatment.

Plague was much more prevalent in 1923 than it was in the previous year; the death-rate per mille rose from 0.4 to 0.8. Certain districts of the Patna and Tihut divisions were chiefly affected.

Small-pox was prevalent in certain districts during the year and the deaths increased from 2,560 in 1922 to 3,161; 407 patients were treated in hospitals.

Deaths from malarial fevers rose from 578,656 in 1922 to 599,840 in 1923 and the death-rate from 17.0 to 17.5 per mille. The total number of patients treated for malaria in hospitals and dispensaries was 932,508 compared with 865,716 in 1922.

Influenza: 26,439 patients were treated for influenza in hospitals and dispensaries in 1923 against 30,191 in 1922. Vaccine was provided by Government to all civil surgeons and superintendents of jails, free of cost, and was available whenever required.

The total number of patients treated for venereal diseases was 64,172 against 62,567 in 1922. A special grant of Rs. 12,000 was given for the purchase of special drugs used in the treatment of syphilis. This grant was distributed to all Sadar and police hospitals and to many subdivisional dispensaries.

Rai Bahadur Dr. P. N. Das continued his investigation in connection with filariasis and read a paper at the Indian Science Congress on the results of his previous year's work. Ninety-two cases were treated by him in 1923, against 90 in 1922, with good results. A special hospital for the treatment of these cases has been built and equipped at Puri.

The number of cases treated for kala-azar increased from 17,212 in 1922, to 20,619. This increase is probably due to patients coming to hospitals more freely for treatment and not to an increase in the prevalence of the disease. The treatment by intravenous injection of various drugs appears to be increasing in popularity in many of the districts where the disease is prevalent.

The cases treated in hospitals and dispensaries for tubercle of the lung numbered 8,924 against 6,825 in

1922, and deaths among them were 131 and 116 respectively. There are no special hospitals for the treatment of these cases.

Ankylostomiasis is prevalent all over the province—the northern districts appear to be more heavily infected than others. During the year a special investigation was commenced by Dr. Korke in the Singhbhum district under the auspices of the Indian Research Fund Association.

In the ten leper asylums at work during the year there were altogether 2,082 resident lepers against 2,010 in 1922.

The number of surgical operations performed during the year under report at the State-public, Local Fund and private-aided hospitals and dispensaries was 206,814 with 346 deaths against 175,164 operations and 252 deaths in 1922.

The total income of the hospitals and dispensaries during 1923, excluding the opening cash balance, was Rs. 22,87,411 against Rs. 17,54,636 in 1922 and the total expenditure, excluding amounts invested during the year, was Rs. 20,69,495 against Rs. 16,98,966 in 1922.

The buildings of the Ranchi Radium Institute were completed and equipped. The successful treatment given in past years has drawn a large number of patients, and the rise in figures shows that the work of the institute is greatly appreciated. There were 189 new cases treated in the year under report against 86 in 1922.

The maternity and child welfare scheme continued to work satisfactorily at Patna under the supervision of Mrs. Duncan White, Maternity Supervisor. A similar scheme has been organised at Cuttack under the auspices of the Red Cross Society.

Reports on the working of the two mental hospitals in the province have been published separately. The construction of the buildings for the mental hospital for Indians at Kanke has made satisfactory progress. Most of the buildings have been completed. The hospital will probably be ready to receive patients in August 1925.

The necessity for a Medical College for the province has been very keenly felt. To supply this long-felt want it was decided to transfer the Temple Medical School from Patna to Darbhanga and establish a new Medical College at Patna. The plans and estimates of the additional buildings required for the college and the attached hospital with their equipment have been prepared.

Eight new posts were added to the cadre of assistant surgeons and the cadre of sub-assistant surgeons was reduced by 9 posts. One assistant surgeon and six sub-assistant surgeons retired during the year. One assistant surgeon resigned the service. The pay of sub-assistant surgeons was revised and an increased rate of teaching allowance was sanctioned for the teachers of medical schools.

REPORT ON THE JAIL ADMINISTRATION OF THE PROVINCE OF ASSAM, FOR THE YEAR 1924. BY COLONEL C. H. BENSLEY, C.I.E., K.H.P., I.M.S., INSPECTOR-GENERAL OF PRISONS, ASSAM. SHILLONG: ASSAM SECRETARIAT PRINTING OFFICE, 1925. PRICE RE. 1.

THERE was a very distinct all-round decrease in the number of prisoners in the jails during the year, as compared with the previous year. One of the most satisfactory features was the reduction in the number of prisoners under the age of 21. There was only one juvenile prisoner. There is very much to be done for the young prisoner in this country. The position of the magistrate is a difficult one on account of the absence of some society to take over charge of these young offenders.

It is unfortunate that it was necessary to send to jail in 1924, 87 lads between the ages of 16 and 18 years and 182 between the ages of 19 and 21 years, mainly for the want of Aid Societies. These lads are at the most impressionable ages of their lives, and where, through constructional defects, separation from adults

SEPT., 1925.]

cannot be carried out thoroughly, the danger of their becoming contaminated during their stay in jail is a very real one. It is useless suggesting Borstal Jails or suggesting improvements in existing jails to bring them up to date and to provide facilities for separation of the classes, when those who fulminate against the jail administration in this province at the same time begrudge the expenditure of money on the most necessary requirements to permit of the introduction of the most elementary rudiments of jail administration.

It is for public enterprise to start these Discharged Prisoners' Aid Societies, if they are to meet with any success. Probably, Government would give a small grant to any which were proving their utility in aiding to keep first offenders, both adolescent and adult, out of jail, and in giving a helping hand to released prisoners in the first few months of their freedom and so prevent them returning to jail. It is public spirit and enterprise which is required, and it is the presence or absence of this which will be the proof whether the sentiments expressed by a section of the public are sincere or not.

Discharged Prisoners' Aid Societies will not be successful if run by Government through its own servants; such influence would be misunderstood by prisoners once they are released.

Death.—The rate for the year is 19.51 per mille. This is the lowest figure for a number of years. It is however still well above the average death-rate for jails all over India. The total number of deaths was 46; the largest number from any one disease being 9 from pulmonary tuberculosis. Pneumonia was the cause of 7 deaths and dysentery 6. No deaths from kala-azar were reported.

Sickness.—The sickness rate 29.48 per mille is the lowest that has been recorded during the last 10 years. The largest number of admissions was for malaria and the next largest for diarrhoea. There were 28 cases of pneumonia with a 25 per cent. death-rate and 16 of pulmonary tuberculosis with a death rate of over 56 per cent.

55 per cent. of prisoners gained in weight during their stay in jail and only 20 per cent. lost in weight; the balance retained their original weight.

The medical statement can be looked upon as very satisfactory. The one somewhat alarming feature is the number of cases of pulmonary tuberculosis and the high death-rate amongst them. An interesting point is the fact that kala-azar is not given a separate heading in the table showing the cases of sickness and death from the chief disease nor is the disease anywhere mentioned as a cause of sickness or death amongst the jail population.

THE FIFTH ANNUAL REPORT OF THE CENTRAL CO-OPERATIVE ANTI-MALARIA SOCIETY, LTD., CALCUTTA.

THIS Society, as probably most of our readers are aware, was started in 1917 by a number of enthusiastic medical men to show the people in the rural districts of Bengal how to protect themselves against the dragon that has for many years been preying on the villagers of Bengal—*Malaria*. Amongst the prime movers were such men as Sir Kailas Chandra Bose, Dr. C. A. Bentley and Rai Bahadur G. C. Chatterjee. With such men at its head the movement was certain to obtain a sufficiency of followers as long as the necessity for their activities existed. Unfortunately this necessity does exist and we fear may continue to exist for many years. The report for 1924 shows this and also shows the wonderful way in which this necessity has been met. The history of the Society tells of a series of giant strides,—in 1918 the work was being carried out in eight villages, in 1923 in 82 villages and in 1924 in 360 villages. The Society first started as a purely voluntary Society, most of the workers were entirely unpaid and the medicine and appliances were supplied

by funds collected privately. The Bengal Government now gives this Society a substantial subsidy but it would be impossible for it to carry out the work which it is doing if much of the work that is done was not entirely unpaid.

The last year's report has demonstrated one point, the versatility of the Society. These modern St. Georges went forth to slay one dragon but they found that another dragon existed—apparently a somewhat more rapacious dragon—*kala-azar*. With great good sense they divided their forces and turned their attention to the treatment of this disease also; the returns for 1924 show that nearly 20,000 of cases of kala-azar were treated during the year. This fact surely must be a revelation to the health authorities who only a couple of years ago estimated the kala-azar cases for the whole province at 50,000.

The working of the Society reflects great credit in its founders and also on its energetic Secretary, Rai Bahadur Dr. G. C. Chatterjee.

CALCUTTA DENTAL COLLEGE AND HOSPITAL. ANNUAL REPORT FOR 1924-25. BY R. AHMED, D.D.S.

THIS institution was founded in 1920 and has already students from all over India on its books, the present number being 22, with accommodation for not more than 50 altogether. A syllabus has been drawn up with special regard to Indian requirements. The institution is entirely self-supporting and has not received any grants from government or other sources. The annual fee of Rs. 500 may seem high, but not when the cost of equipment and accessories is considered. During the year 1920 attendances were made by patients and an enquiry was made into the dental condition of students in the Calcutta schools and colleges. Quite 75 per cent. of them were found to have dental defects, and one of the chief aims of the institution is to arouse attention to this very important problem.

Correspondence.

A HINT ON THE TRANSMISSION OF KALA-AZAR.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—I would like to bring the following facts to the notice of those who are engaged in the kala-azar transmission problem.

I find in my inspection of kala-azar infected villages of Tipperah District that the disease is specially prevalent amongst the poor people who are living in insanitary conditions regarding their personal hygiene, and in small, dirty and overcrowded huts, thus in close contact with patients.

The condition that is responsible for the spread of typhus and relapsing fever is generally present in this case too. I intend to give prominence to the interesting fact that in every infected area *dhobies* and barbers are particularly attacked. In some villages they have started the disease and in an infected locality it is rare to find a *dhobie* or a barber remaining unaffected.

I think a close search for the parasite in lice from the patients may help us to find the agent, because *dhobies* and barbers are persons who are most liable to be infected through this agent. Although the disease is known to attack persons of cleaner habits yet the louse may be one of the agents to spread the disease.

The difficulty in checking the spread of kala-azar cannot be solved unless the cause of transmission is ascertained. At present we are solely dependent on the successful treatment of a kala-azar patient by disinfecting the blood with antimony; but this is an expensive affair, neither is it perfect, because all patients will not

come for treatment at the same time. When there are, say, three cases in a family, one may attend while the rest watch the result of his treatment before they dare to come themselves for treatment. The infection is thus spread to many others while they mark time. Under the above circumstance compulsory attendance at centres by the introduction of an Infectious Diseases Act is necessary to prevent its spread till we find the means of transmission.

I have noticed that the death rate from fevers, and consequently the total death rate, can be lowered by treating kala-azar cases alone. If we can prevent the spread of this disease it is certain the death rate will decrease at once and there will also be an increase in birth rate of this province.—Yours, etc.,

A. K. MUKERJI,
District Health Officer, Tipperah.

COMILLA,
30th April 1925.

COMPRESSION OF THE EYEBALL BEFORE CATARACT OPERATION WHEN ESCAPE OF VITREOUS OR CHOROIDAL HÆMORRHAGE IS APPREHENDED.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—May I request you to publish the following note?

A drop of 4 per cent. cocaine lotion with which a little adrenalin is mixed is instilled into the eye before operation. The patient lies on his back with his chin raised and closing his eye presses it backwards fairly firmly with the tips of his fingers. He is not likely to cause excessive pressure. Another drop is instilled about 8 minutes afterwards and pressure continued. In 15 or 20 minutes he is ready for operation. I have now stopped pressing the eyeball myself; the patient does it.

I wrote a short note on the subject, which was published in the *Indian Medical Gazette* for June 1923, but cataract surgeons do not appear to have noticed it. This simple and harmless measure reduces the tension considerably.

Captain Cruickshank, I.M.S., has mentioned this step in his article on "Choroidal Hæmorrhage following Cataract Extraction" in the *Indian Medical Gazette* for May 1925, hence this note.—Yours, etc.,

HARI SHANKER, R.B., I.M.S.

MUTHRA, U. P.,
11th May 1925.

RELAPSING FEVER AND DYSENTERY.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—Towards the latter part of an epidemic of widespread relapsing fever on the Nilgiris I had occasion to meet with a number of cases of dysentery occurring in relapsing fever patients. Such cases were not met with in the early days of the epidemic. A day or two previous to the fall of temperature of the first pyrexial period, more often at the beginning of the apyrexial period, dysentery starts. The patient has very frequent stools of blood and mucus; there is more blood than mucus. Motions average about 30 to 40 in 24 hours. If the complication starts in the pyrexial period the usual novarsenobillon or sulfarsenol injection cures the dysentery also, but difficulty arises when the dysentery starts in the apyrexial period. In the apyrexial period when spirilla are not present in the peripheral blood the injection does more harm than good. In the increased toxæmia of the apyrexial period the shock of reaction after the injection very often kills the patient. Even if the patient survives, injection at this stage does not alter the course of the fever nor of the dysentery. I have repeatedly examined these stools for amœbæ but have not been able to find them. Very often in a stained specimen of the stool the spirillum of relapsing fever has been found. This was probably because there was blood in the stool.

I did not make an examination for *B. shiga* because I did not suspect that bacillary dysentery would have a partiality to relapsing fever patients.

I have not had occasion to do a post-mortem on a case that ended with dysentery and therefore do not know of the pathological changes in the intestine.

What I used to do by way of treatment—with success—in apyrexial cases was to give frequent astringent bowel washes,—Pot. permanganate pills, Pulv. Doveri—in suitable cases. Vigorous symptomatic treatment is essential to save the patient from collapse and death during this period. Castor oil emulsion and emetine have been tried, but without much success. When the temperature again rises an injection of sulfarsenol saves the patient.

I would like to hear from those more experienced in relapsing fever whether they have noticed this frequent complication and whether the spirilla do cause a specific ulceration of the bowel. Further investigation would be an advantage.—Yours, etc.,

T. K. KOMAN NAIR, L.M.P.,
Medical Officer, Kotagiri.

(Formerly in charge of Relapsing Fever Operations, The Nilgiris.)

THYROID EXTRACT IN THE TREATMENT OF NEPHRITIS.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—With reference to Dr. Eapen's invitation to your readers to express their opinion on thyroid extract in nephritis, I would like to say it has been completely disappointing in mine.

Last year a British officer was under treatment for subacute parenchymatous nephritis with severe anasarca. Diuretin, digitalis (there was some cardiac involvement also), and thyroid extract all had their turn, with no relief. It was eventually decided to give tincture of Apocynum, the famous vegetable trocar, a trial and within a week the patient was a different person. I don't pretend to aver that there was a cure; the case was too far gone, but from intense anasarca and ascites to a tolerably comfortable state is a great advance.—Yours, etc.,

B. J. BOUCHE,
Assistant Surgeon, I.M.D.

JUTOGH, SIMLA HILLS,
15th April 1925.

INTRAVENOUS PITUITRIN.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—In your issue for March 1925, Dr. S. Serhachar writes that as a result of a hypodermic injection of 1 c.c. of pituitrin in a puerperal patient, the patient had some unpleasant symptoms, such as intense and sudden pain of a stabbing character in the right side of the chest and back, orthopnoea, paleness of face and slowing of pulse. He attributes these symptoms to "air embolism of the right pulmonary artery" as a result of "dislodged clots occluding the orifices of some of the vessels in the uterine wall" consequent on the sudden rise of blood pressure.

Again in your issue for June 1925, Dr. D. M. Vasavada states he had also experienced similar symptoms in two of his cases and that these symptoms occurred after an intravenous injection of pituitrin. From the occurrence of these symptoms he concludes that "pituitrin is not for intravenous use and the further it is kept from a vein the better."

When one understands the pharmacology of pituitrin it is not difficult to find the cause of the above symptoms. Personally I do not think they were due to air embolism as suggested by Dr. Serhachar. Pituitrin when given either hypodermically or intravenously contracts the coronary arteries of the heart and has a depressant action on the cardiac muscle. Thus when pituitrin is administered it manifests its action on the heart: (1) by constriction of the coronary vessels, which lessens the

flow of blood to the heart muscle; (2) by inducing a great rise of blood pressure, which throws an additional burden on the heart and consequently slows the pulse; and (3) by a direct depressant action on the heart muscle.

I think the alarming symptoms experienced by these two doctors were due to the above actions of pituitrin on hearts which had been damaged previously from some cause.

Personally, I have given about 100 intravenous injections of pituitrin. In some cases 1 c.c. and in others $\frac{1}{2}$ c.c., along with normal or hypertonic saline, were given according to the indications in collapse of cases of gastro-enteritis. In not one single case have I met with any of the above alarming symptoms consequent on the intravenous use of pituitrin. I admit I have never given pituitrin in the pure form, undiluted, intravenously, but I can safely assert that pituitrin given in a dilute form will never cause any unpleasant symptoms.

According to present-day therapeutics pituitrin is one of the most potent and valuable drugs, especially in a case of emergency. To condemn such a useful drug for intravenous use without knowing its pharmacological actions is very unjust. One must be very careful and think twice before administering pituitrin when there is any affection of the heart muscle present.—Yours, etc.,

Y. S. ROW, L.M.P.

ALIPURAM JAIL HOSPITAL, BELLARY.
19th June 1925.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Colonel A. A. Gibbs, I.M.S., to be Honorary Physician to the King, Indian Military Forces, *vice* Major-General J. Jackson, C.I.E., M.B., I.M.S. (Retired), 24th September 1924.

Colonel E. L. Perry, D.S.O., I.M.S., to be Honorary Surgeon to the King, Indian Military Forces, *vice* Colonel F. Wall, C.M.G., I.M.S. (Retired), 5th March 1925.

Lieutenant-Colonel K. V. Kukday, I.M.S., Officiating Surgeon-General with the Government of Bombay, is appointed to be Inspector-General of Civil Hospitals, Central Provinces, with effect from the date on which he assumes charge of his duties.

The services of Major R. V. Morrison, M.D., I.M.S., are placed temporarily at the disposal of the Government of Burma, with effect from the date on which he assumes charge of his civil duties.

Major J. Morison, M.B., I.M.S., is appointed to officiate as Director, Bombay Bacteriological Laboratory, with effect from the date on which he assumes charge of his duties.

The services of Captain T. H. Thomas, I.M.S., are placed temporarily at the disposal of the Government of the Punjab for employment as Superintendent, Punjab Mental Hospital, Lahore, with effect from the date on which he assumes charge of his duties.

The services of Captain G. B. Hanna, I.M.S., are placed temporarily at the disposal of the Government of Bengal, for employment in the Jail Department, with effect from the date on which he assumes charge of his duties.

The services of Captain K. R. Rao, I.M.S., are placed temporarily at the disposal of the Government of Madras, with effect from the date on which he assumes charge of his civil duties.

PROMOTIONS.

Lieutenant-Colonel (now Major-General) H. J. K. Bamfield, C.B., D.S.O., K.H.P., to be acting Colonel, while holding the appointment of Assistant Director, Medical

Services, 5th Cavalry Division, Egyptian Expeditionary Force, from 12th February 1919 to 28th February 1920.

Major (now Lieutenant-Colonel) J. S. O'Neill, M.C., M.D., I.M.S., is granted the acting rank of Lieutenant-Colonel from 27th December 1915 to 12th January 1916 whilst serving with an Indian Field Ambulance in Mesopotamia.

Captain (now Lieutenant-Colonel) J. S. O'Neill, M.C., M.D., I.M.S., is granted the acting rank of Major from 29th April to 5th May 1915, whilst serving with an Indian Field Ambulance in France.

To be Captain.

Malcolm Frank Douglas Graham, 22nd December 1923, but to rank from 13th July 1923. London Gazette notification dated 11th January 1924, is hereby cancelled).

We congratulate the following whose names appeared in the last Birthday Honour's List.

C. S. I.

Major-General T. H. Symons, Surgeon-General, Government of Madras.

C. I. E.

Lieutenant-Colonel R. P. Wilson, Offg. Surgeon-General, Government of Bengal.

Lieutenant-Colonel C. A. F. Hingston, Superintendent, Government Hospital for Women and Children, Madras.

Khan Bahadur Behramji Hormasji Nanavati, Medical Practitioner, Ahmedabad.

C. B. E.

(Civil Division).

Major A. J. H. Russell, Director, Public Health, Madras.

O. B. E.

(Military Division).

Major J. Scott, D.S.O., I.M.S.
Senior Nursing Sister Miss M. Wardell, Queen Alexandra's Military Nursing Service for India.

M. B. E.

(Civil Division).

Agnes Dorothea, Mrs. Haskell, St. John's Ambulance Nursing Division, Bengal.

Major H. Mansfield, Deputy Superintendent, Campbell Medical School and Hospital, Calcutta.

Saravaiya Amritraj Esquire, Health Officer, Civil and Military Station, Bangalore.

Lieutenant J. C. Chalke, Assistant Surgeon to His Excellency the Governor of Bengal.

Subedar-Major Barkat Ram, Bahadur, Indian Medical Department.

Kaisar-I-Hind Medal (First Class).

Miss W. Spicer, Lady Superintendent, Lady Minto's Indian Nursing Association and Matron of the Railway Hospital, Ajmer, Rajputana.

Dr. E. G. Bare, Clara Swain M. E. Mission Hospital, Bareilly, United Provinces.

Mother Henrietta in charge of the Nurses at the Ranchi Sadar Hospital.

Dr. E. L. Young, in charge, Palwal Mission Dispensary, Gurgaon District, Punjab.

Kaisar-I-Hind Medal (Second Class).

Doctor (Miss) Rukmabai, Zenana Medical Officer, Kathiawar, Western India States Agency.

Miss W. E. Walters, Lady Superintendent, Civil Hospital, Karachi, Bombay.

Miss A. Burton, Lady Superintendent, Lady Minto's Indian Nursing Association, Murree, Punjab.

Rao Sahib C. M. Mudaliar, Private Medical Practitioner, Secunderabad, Hyderabad, Deccan.

Babu Hari Mohun Mukherji, Medical Practitioner and Chairman, Krishnagar Municipality, Bengal.
Miss Elizabeth Mary Newman, Nurse, Rainawari Hospital, Kashmir.

Khan Bahadur.

Assistant Surgeon Khan Sahib Mir Hidayat Ullah, Medical School, Amritsar.

Rai Bahadur.

Babu Nani Lal Pan, Upper Bengal Medical Service, Professor of Anatomy, Medical College, Calcutta.

Rai Sahib Sarup Narayan Mathur, Civil Surgeon, Unao, United Provinces.

Babu Sanat Kumar Barat, Civil Assistant Surgeon, Bihar and Orissa.

Honorary Captain Rai Sahib Maharaj Krishna Kapur, Practitioner, Lahore.

Rao Bahadur.

M. R. Ry. Arcot Lakshmanaswami Mudaliyar Avargal, Assistant Superintendent, Government Maternity Hospital, Madras.

Shifa-ul-Mulk.

Hakim Abdul Hamid, Physician, Lucknow.

Sardar Sahib.

Assistant Surgeon Bhai Sohan Singh, Medical School, Amritsar.

Khan Sahib.

Muhammad Omar Sahib Bahadur, Senior Assistant, King Institute, Guindy, Madras.

M. Muhammad Hakimullah, Sub-Assistant Surgeon, North-West Frontier Province.

Subadar Major Raffi-ud-din, Indian Station Hospital, Abbottabad.

Rai Sahib.

Pundit Nilambar Joshi, Medical Officer, in charge of the Hatras Dispensary, Aligarh District, United Provinces.

Babu Lekh Raj Singh, Sadar Hospital, Aligarh.

Shadi Ram Sondhi, Sub-Assistant Surgeon, Baluchistan.

Rao Sahib.

M. R. Ry. Bonaventura Colaco Avargal, Civil Apothecary (Retired), Mangalore, Madras Presidency.

Ahmudan-gaung Tazcik-ya-Min.

U. San Kyaw, Sub-Assistant Surgeon, Mandalay, Burma.

NOTICES.

A NEW ZEISS MICROSCOPE.

MESSRS. CARL ZEISS have recently issued a new microscope suitable for advanced research workers. This is a large stand suitable for photomicrography, the body tube is large, the fine adjustment is of the New Meyer clockwork type, and in other respects the instrument is similar to the well-known large Zeiss models.

It is pleasing to note that microscopes of the highest class are once more available at about pre-war prices.

Full details of this and other microscopes can be had from the Agents, Messrs. Adair, Dutt & Co., Ltd., 5, Dalhousie Square, East, Calcutta.

ANTIPHLOGISTINE.

We have received from the Denver Chemical Manufacturing Company, 20, Grand Street, New York, U. S. A., a sample of the well-known and popular product known as antiphlogistine. This is very widely used by medical men in India and needs no special introduction to our readers, all of whom must be familiar with the use of antiphlogistine in the treatment of inflammatory conditions.

'HYPOLOID' BISMUTH METAL.

'HYPOLOID' Bismuth Metal in Isotonic Glucose Solution (0.2 gm. in 1 c.c.) is prepared by Burroughs, Wellcome & Co., to provide specialists and general practitioners with an additional weapon in their campaign against syphilis.

It presents metallic bismuth—now recognised as a definite spirillicide—in the form best suited for intramuscular injection and removes several objections which have militated against the use of some other bismuth preparations. The isotonic glucose solution allows uniform absorption to take place and practically eliminates abscess formation if the usual technique for intramuscular injection is observed.

The required dose is drawn up direct into the syringe barrel by puncturing the rubber cap with the syringe needle and withdrawing the piston to the requisite mark on the barrel. On withdrawing the needle the aperture in the rubber cap closes automatically and reseals the container.

Burroughs, Wellcome & Co., announce two sizes of 'Hypoloid' Bismuth Metal in Isotonic Glucose Solution, No. 556—1 c.c. Rubber Capped Bottles and No. 527,—10 c.c. Rubber Capped Bottles. The commencing dose suggested is 1 c.c. at each injection.

BRITISH MEDICAL ASSOCIATION MEETING, BATH 1925.

"Tabloid" "Iodidin" gr. 3 presents the same chemical substance—calcium iodo-ricinoleate—as a capsule product, and each product secures the administration of 1 gr. of iodine. "Ethidol"—ethyl iodo-ricinoleate—is an allied product containing 20 per cent. of iodine for use by inunction or by injection into sinuses or cavities.

Amongst additions to the list of "Tabloid" products "Tabloid" Digitalis Leaf, which presents the whole substance and activity of selected digitalis leaves and which is, in the opinion of many clinicians, more reliable than fluid digitalis preparations and "Tabloid" Hexamine and Methylene Blue were particularly to be noted.

The pioneers of "Kharsivan," the first British Salvarsan, have introduced recently a new member of the arsenobenzol series which greatly facilitates the technique of administering these powerful spirillicides. This is "Kharsulphan" which may be given hypodermically or intramuscularly, and which will be specially welcomed by practitioners as a reliable antisyphilitic obviating the elaborate technique for intramuscular injection.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints gratis, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to the *Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of the *Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

ACUTE INFLAMMATION OF THE PROSTATE.

By HENRY SMITH, C.I.E.,

LIEUTENANT-COLONEL, I.M.S. (Retd.),

Sidcup, Kent.

THIS is a subject which receives very little consideration in books dealing with genito-urinary diseases. One would think when reading the sections dealing with this subject that this disease must be very rare. In actual practice this is not the case.

I have operated on as many as three cases which came in on the same morning. It may not be just so frequent as this might suggest; at the same time acute inflammation of the prostate is more frequently misdiagnosed than any other case in surgical practice. The result of this is that the case is temporised with and allowed to declare itself by an abscess opening into the rectum or into the bladder.

Many years ago when I was stationed at Jullundur, the wife of a clergyman of my acquaintance in the West of Ireland wrote to me at the dictation of her husband that a few days previously he had driven some ten Irish miles on an outside car, exposed to storm and sleet the whole way; that that night he had to send for the doctor on account of retention of urine; that he had emptied the bowels as there was a desire to do so. Though the urine was periodically drawn off there was a constant desire to go to stool though the bowels were empty—also constant pain in the breech. He was 45 years of age. I wrote to her by return post saying that it was a characteristic case of acute inflammation of the prostate and that the local doctors would, of course, deal with it.

Such was not the case. Two general practitioners were in attendance and the nearest consulting surgeon was called in. The wife pressed for a diagnosis as the case was not doing well, but she could get none. Then she insisted on having a consultant from Dublin (these men are all since dead) to which they gave way. When he arrived he passed a finger into the rectum to find that the abscess had burst into the rectum. My letter had just arrived and was put into his hand. He left saying that all would now be well. It was thus about six weeks from the beginning of the illness till it burst. All was not well. The patient died within three days. It is not to be inferred that such failures in diagnoses occur only in Ireland. I know an important Indian official (European) who,

when on leave in England, went into a nursing home in London and had seen a number of consultants who also temporised. The patient set out for India and the abscess burst in the Suez Canal.

The above case presented the usual symptoms:—Rapid onset of retention in a man between 20 and 60 years of age, with pain in the breech and *tenesmus of the rectum*. In drawing off the urine we find no obstruction and no stone. A finger in the rectum in the early stage does not give much information as the capsule of the prostate is dense. After a few days the prostate will feel enlarged. On the group of symptoms above detailed, I have no hesitation in operating and I have never been deceived by them.

The tenesmus of the rectum is the most characteristic of the group.

In operating, I pass a scalpel on the flat from the perineum just in front of the rectum until I reach the prostate and then tilt up the point into the prostate and make a transverse cut in it and enlarge the wound when withdrawing the knife. In doing this the bladder need not be opened.

In those cases which burst into the bladder or rectum, the usual doctrine is that they should be left to drain by that route without further interference. This, in my opinion, is quite wrong.

If the abscess bursts into the bladder, the irritation causes the sphincter to contract and the retention remains and has to be relieved by frequently passing a catheter. The abscess cavity is thus being kept distended with urine which we know to be a very poisonous substance in any such cavity. The same applies to the rectum. The sphincter will contract from the irritation of the pus and the cavity will be pumped full of faecal gases.

The proper procedure (when the abscess has burst into the bladder) is to pass a lithotomy staff and make a small lithotomy-sized wound and drain both bladder and abscess. In case it empties into the rectum, the sphincter should be freely incised and the front wall of the rectum right up to and into the abscess cavity. The proper treatment, of course, is to open the abscess long before it would open of itself.

Causation.—Gonorrhoea is said to be the great cause of this condition. In my experience this is not correct.

ASEPSIS.

By H. HALLILAY,

LIEUTENANT-COLONEL, I.M.S.,

Civil Surgeon, Simla.

If one were asked to describe the difference between the surgical practice up to 1865 and that

which was founded upon the discoveries and principles established by Lord Lister, the answer could be given in one word, "asepsis."

If, however, one were asked how many surgeons personally supervise the sterilising arrangements upon which the achievement of this asepsis is founded he would probably express a pious hope that they all do so.

Yet to quote Macaulay's famous sentence respecting another matter, "unless we greatly err, this subject is to most readers not only insipid but positively distasteful."

I remember once during the war being shown over a recently commissioned hospital-ship by an enthusiastic medical officer who displayed with pride the equipment of the handsome operating theatre.

In the course of my visit to the theatre I happened to ask him at what pressure he was accustomed to sterilise his aseptic dressings, swabs, etc. I shall not readily forget the accents of cold disgust in which he replied "I leave all that sort of thing to the theatre sister."

I think we should not be wrong in assuming that Lord Lister would not have left "that sort of thing" to the discretion of a subordinate.

The Duke of Wellington was accustomed to say when reviewing his achievements as a general, "if I blundered I could always rely on my men pulling me through."

If in a more restricted battle-field a surgeon blunders he can usually rely upon the immense powers of resistance latent in the tissues of the human body to bacterial invasion to cover up any faults of omission or commission in his aseptic ritual.

Is every instance of the occurrence of sepsis in a "clean" operation due to auto-infection?

Sometimes the infection is too heavy and the virulence of the organisms inadvertently introduced by the surgeon so intense that even the heroic resistance of the tissues is overwhelmed.

It is on these occasions that the surgeon comes into unfavourable comparison with the bacteriologist, whose aseptic standards are demonstrably higher.

"What the eye does not see the heart does not grieve after" and the heart of the surgeon is often spared from grieving because his eye has not seen the silent struggle in the tissues from which the victory has emerged which has blotted out all record of his errors.

On the other hand the bacteriologist has no such allies. He stands or falls by the completeness or otherwise of the precautions which he has taken to prevent the contamination of his media; inevitable disaster and exposure follow the smallest mistake.

His media have no inherent powers of resistance to the growth of micro-organisms, on the contrary they are especially designed to foster and encourage such growth.

What bacteriologist would rely on the feeble

and inadequate means for effecting asepsis which satisfy too many surgeons?

When one hears of a "clean" operation going wrong, when a patient who light-heartedly entered a nursing home to undergo an operation which he was assured would prevent him from following his usual pursuits for at most a few weeks is condemned to months of fever, insomnia, pain, the risk of an incisional hernia, of death itself, the failure of the operation because there was a breakdown in the aseptic arrangements, can any precaution, any care be considered too meticulous?

If every one of these septic misadventures were made the subject of an official inquiry by a properly constituted court as is done after a naval disaster, we should hear of fewer of these regrettable incidents which at present disfigure too often the fair fame of aseptic surgery; certainly the attitude of the profession at large to them would become far less tolerant.

When the cult of asepsis displaced that of antiseptis in the ritual of surgical operations all over the world, and the plain gauze swab sterilised by steam at high pressure ousted the marine sponge saturated in some germicidal solution from its pride of place, then the H.P. (high pressure) steriliser came into its kingdom. Its importance indeed in the aseptic scheme can hardly be exaggerated. On it depends the sterility of the gauze swabs which are actually introduced into the wound, the towels which are clipped to its edge, the aprons of the surgeon and his assistants, and frequently the gloves which cover their hands.

If for any reason it fails to sterilise and organisms are inadvertently introduced into the wound, the only protection against disaster is the resistance of the patient's tissues.

The modern H.P. steriliser as supplied by the surgical instrument manufacturer is usually provided with a manometer to register the pressure and a thermometer to record the temperature. The reading on these instruments relates to the temperature and pressure in the chamber of the steriliser, those obtaining in the middle of the drum amongst the towels and dressings may be widely different. What the manufacturer does not provide is any means of gauging the temperature to which the dressings have been subjected inside the drum.

In view of the fact that it is possible to expose the outside of a drum to a temperature of 121°C. and for the temperature within the drum to rise only to 97°C. after 10 minutes, it is obvious that a pyrometer which registers the maximum temperature arrived at in the middle of the drum is a desirable safeguard.

Various pyrometers have been suggested; some, such as flowers of sulphur, which show a change of form as soon as the required temperature is reached. Sulphur, for example, melts at 114.5°C.

Others are of the nature of colour indicators, changing colour at a constant temperature specific for the substance. The use of tubes of phthalic acid has been recommended; this

substance is said to turn bright red at high temperatures. I have no experience of this compound but according to Black (1925) it does not work satisfactorily in practice, for this author states that after carrying a packet of it in his waistcoat pocket for a few hours it developed a fiery red!

Others again depend on a combination of the two foregoing devices such as a mechanical mixture of antifebrin and methylene-blue in the proportion of 2 grains of the latter to 1 ounce of the former.

This mixture is said to remain white up to a temperature of 230°F. (110°C.) when it develops an intense blue colour. Obviously the test depends on the dye going into solution as soon as the antifebrin melts and on its diffusion throughout the crystals. The melting point of antifebrin is officially 114°C., but this of course means that of the drug in a chemically pure state; the admixture of the methylene-blue naturally alters the melting point. I have tested this indicator and find that many fallacies are involved in its use. In the first place it can only be used in sealed glass capsules because the mixture turns a vivid blue at the faintest trace of moisture. Secondly, it does not turn blue at 110°C. but at 105°C. These results were arrived at after testing the mixture very carefully with a thermometer specially made for these experiments by Mr. S. Woodhouse, Officer-in-Charge, Mathematical Instrument Office, Calcutta, for whose great trouble and kindness in this connection I take this opportunity of expressing my most grateful thanks.

The ideal indicator, if one is to come into general use, should be cheap, easily available, not altered by moisture so as to necessitate the provision of glass capsules and of a melting point of 114°C.

An indicator answering to these requirements is to be found in powdered sulphur which melts at a temperature of 114.5°C., is unaffected by moisture and is to be found in every hospital and dispensary all over the civilised world.

A small paper packet of flowers of sulphur placed in the middle of the dressings to be sterilised will set the mind of the most conscientious surgeon at rest if, on opening the drum, he finds that the sulphur has fused. He can at any rate rely upon it that the swabs and dressings he is about to use are above reproach as regards sterility.

This device safeguards the dressings and the swabs inside the drum. A further one is desirable. I refer to the chance of the drum being opened by any unauthorised person after the sterilisation is complete.

This again can be effected by the use of a sulphur seal. Make up some starch paste by pouring boiling water on starch, the water must be boiling as otherwise the capsule of the starch granule will not burst, stir in an equal quantity of sulphur powder and paste a couple of strips of paper over the lid on to the side of the drum.

If the sterilisation has been properly carried out the sulphur in the paste will melt and seal the paper on to the lid and sides of the drum so that it will be impossible to open the drum without breaking the seal.

It may be objected that these precautions are unnecessary and irritating, but after all they are fewer and simpler than the safeguards employed by a bank in its own protection when dealing with the transfer of valuables or securities, and in view of the magnitude of the issues at stake can any precaution be considered excessive?

Theoretically, those to whom this highly important operation of sterilising is entrusted are infallible. Theoretically, all are honest until they are proved to be rogues, but does any one in the knowledge of this axiom of British law consider that he is justified in resenting the conduct of a bank manager in demanding a signed receipt before he will cash a cheque for the most valued and respected client?

The business of sterilising is of so important a nature that it should be conducted with the vigilance and severity with which a bank manager conducts the business of his bank, nothing should be taken on trust and nothing left to chance.

The next fallacy with regard to sterilising lies in the fact that if the drums are packed too tightly the rate of heat penetration is very greatly slowed, in fact, it is possible to conceive of a degree of tightness which would prevent the heat penetrating at all.

If Table III be consulted it will be seen that a tightly packed drum if exposed to a temperature of 121°C. for 10 minutes will only register a temperature of 97°C. in the centre of the dressings.

This of course would be an entirely inadequate temperature should the dressings or swabs have been contaminated by spores or spore-forming organisms though it would probably be sufficient for the ordinary pyogenic organisms.

The temptation to overload steriliser drums is great, because the type of steriliser usually found in hospitals and institutions is far too small and in order to get the drums sterilised up to time there is a tendency to pack the drums to their utmost capacity short of bursting the hinges off the lids, and worse still, to cut short the time of exposure.

It is to be borne in mind that it is the practice in many institutions and nursing homes to cut up ordinary gauze or muslin and to use it for swabs and dressings after they have been sterilised in the institution steriliser. When one considers the possibility of contamination in the manufacture and transport of these fabrics, sure indeed must he be of the efficiency of his sterilising arrangements before he dare introduce any of this material into the abdominal cavity of his patients.

If the fourth experiment in Table IV is referred to it will be seen that after an exposure of 30 minutes to a temperature of 129°C. the

temperature in the middle of the drum rose only to 117°C. a "lag" of about 12°C. as regards temperature. If the results in Table III are studied it will be seen that the "lag" as regards time is about 11 minutes, in other words it takes 11 minutes even at the comparatively high pressure of 20 lbs. for the temperature in the middle of the dressings to reach 114°C., the temperature outside the drum being 126°C.

Experiments (1), (2) and (3) in Table II show that it is possible to obtain a vigorous growth of anthrax and of the spore-forming rice bacillus after an exposure of 10 minutes to a temperature of 115°C.; the culture of staphylococcus was however killed.

CONCLUSIONS.

(1) The majority of H.P. steam sterilisers are too small, from this arises a temptation to overload the drums, this overloading results in a proportionate slowing down of the rate of penetration of heat to the centre of the dressings. It also leads to a tendency to cut down the time of exposure to a minimum varying with the limitations imposed by the conscience or aseptic tenets of the person in charge of the sterilising operations.

(2) The pressure at which so-called H.P. sterilisers are worked is too low to give a comfortable margin of security; a pressure of 30 lbs. is necessary.

(3) To ensure absolute safety and certainty it is most desirable to provide every steriliser drum with a cheap and efficient pyrometer.

Such a pyrometer is to be found in a small packet of flowers of sulphur which should be introduced into the middle of the dressings. A piece of black thread tied to the centre of the packet and leading to the top of the dressings will enable it to be withdrawn without disturbing the contents of the drum. This should be done as soon as the drum is opened.

(4) A set of rules should be drawn up, printed in large type, framed, and hung up in a conspicuous position in the sterilising room. These rules should prescribe in the clearest language the pressure at which the steriliser is to be worked, the time of exposure of the drums after the desired pressure is registered by the manometer and, most important of all, the number of articles which can be introduced into any one drum without dangerously retarding the rate of penetration.

The rules might appropriately end with the following warning:—"It is easier for a rich man to enter the Kingdom of Heaven than it is to sterilise dressings at the centre of a tightly packed drum."

I desire to express my obligation to Major H. W. Acton, I.M.S., for many valuable suggestions in connection with this paper and for his assistance in the bacterial portion of the research which I could not have carried out without his help. Also to Dr. K. Banerji, M.B., D.T.M., for the

sacrifice of much of his own time in supervising these experiments.

Black, K., 1925.—A Weak Point in Sterilising Methods. *British Med. J.*, January 31st, p. 210.

TABLE I.

Series of experiments showing results of exposure of rice bacillus spores to varying temperatures in an H.P. (high pressure) steriliser,—capsule of flowers of sulphur used as pyrometer.

Temperature.	Exposure.	Growth.	Sulphur.
(1) 115°C.	10 minutes	Yes	Not fused.
(2) 121°C.	10 minutes	Yes	Not fused.
(3) 126°C.	10 minutes	No	Fused.
(4) 115°C.	30 minutes	Yes	Not fused.

Note.—The steriliser drug was filled with surgeons' aprons but not so tightly packed that the lid would not close without force. The spores were placed in the middle of the dressings and the flowers of sulphur in sealed tubes by the side of the spores. The organism was a spore-forming bacillus isolated by Major Acton in connection with his beriberi research.

TABLE II.

Results of exposure of anthrax spores, rice bacillus spores and staphylococcus to various temperatures in an H.P. steriliser. Sulphur pyrometer.

Temperature.	Exposure.	Anthrax spores.	Staphylococcus.	Rice bacillus.	Sulphur.
(1) 115°C.	10 mins.	Growth	Unfused.
(2) 115°C.	10 mins.	Growth	Unfused.
(3) 115°C.	10 mins.	..	No growth	..	Unfused.
(4) 115°C.	30 mins.	No growth	Unfused.

Note.—The anthrax spores used in these experiments were found to survive boiling for 35 minutes.

TABLE III.

Series of experiments showing "lag" time as regards the rate of penetration of heat into a well packed drum. In this series of observations two sulphur pyrometers were employed, one on the outside of the drum and the other in the centre of the dressings.

Pressure.	Time.	Outside capsule.	Inside capsule.	Temperature.
(1) 15 lbs.	10 mins.	Sulphur fused.	Sulphur not fused.	120°C.
(2) 15 lbs.	2 mins.	Do.	Do.	120°C.
(3) 20 lbs.	2.5 mins.	Do.	Do.	126°C.
(4) 20 lbs.	7 mins.	Do.	Do.	126°C.
(5) 20 lbs.	9 mins.	Do.	Do.	126°C.
(6) 20 lbs.	10 mins.	Do.	Do.	126°C.
(7) 20 lbs.	12 mins.	Do.	Sulphur fused.	126°C.

Note.—It takes therefore about 11 minutes for even such a comparatively high temperature as 126°C. to penetrate to the middle of a moderately tightly packed steriliser drum.

TABLE IV.

Series of experiments with sulphur pyrometer in which the temperature inside the drug was recorded by a mercurial thermometer.

Temperature.	Time.	Outer capsule.	Inner capsule.	Thermometer in drum.
(1) 115°C.	10 mins.	Sulphur fused.	Sulphur unchanged.	97°C.
(2) 115°C. for 20 mins. raised to 123°C. for 10 mins.		Do.	Sulphur fused.	119°C.
(3) 120°C.	10 mins.	Do.	Sulphur unchanged.	97°C.
(4) 129°C.	30 mins.	Do.	Sulphur fused.	117°C.

Note.—In experiment (2) the drum was purposely loosely packed, in experiments (1), (3)

and (4) the drums were tightly packed. These experiments show that even with such a high temperature as 120°C. operating for 10 minutes the temperature in the centre of the dressings is only 97°C. in a tightly packed drum. On the other hand, with a temperature of 129°C. acting for 30 minutes the temperature recorded by the special thermometer recorded 117°C.—a "lag" in temperature of about 12 degrees.

This result points the moral that to secure a comfortable margin of security the temperature at which the sterilisation is conducted should be far in excess of that usually employed.

A temperature of 129°C. entails a pressure of 30 lbs. to the square inch though this is a great deal higher than many of the so-called H.P. sterilisers on the market are designed to stand.

THE STAPHYLOCOCCAL KIDNEY IN CHILDHOOD.

By E. H. VERE HODGE, M.B.,

MAJOR, I.M.S.,

Surgeon to H. E. the Governor of Bengal.

The physician who is called upon to treat any considerable number of children cannot fail to be impressed with the vulnerability of the kidney in early life.

All types of infection of the upper urinary tract are met with, from the fulminating septicæmic type to *B. coli* infections, at times dangerous to life, but occasionally so mild in effect as to give rise only to occasional attacks of possibly unexplained fever.

The septic kidney of childhood may be clinically classified as follows:—

1. The pyelitis and pyelonephritis of infancy.
2. Intercurrent infection in the course of an acute generalised bacterial infection, as in typhoid.
3. Infection by the *B. coli* group in older children.
4. Infection by pyogenic organisms, more commonly staphylococci, secondary to infection of the tonsils, in older children.

This article is written with the object of calling attention to a particular and dangerous group which is the staphylococcal pyelitis and pyelonephritis of early childhood, in which there is direct evidence of a primary focus of infection, that infection being the tonsil.

It is of prime importance that these cases should be recognised early, as on such recognition depends the ultimate result.

The following four cases will serve to illustrate the type. In three of these cases there is definite evidence that the tonsil was the primary focus, and in the fourth the evidence is rather more than presumptive. They constitute further evidence of the gravity of acute tonsillar infections in children.

These particular cases ended happily, but it is not always thus; there are fulminating cases,

accompanied by septicaemia, which progress rapidly to a fatal termination.

A feature of two of the cases is the marked acetone reaction in the urine in the early stages of the disease. It is presumed that this has no special significance, but it is the acetonuria which often accompanies the onset of acute diseases in children to which, conceivably, the occurrence of convulsions may be attributed.

At the same time, such acetonuria cannot be neglected, and it is perhaps wise to direct the attention to this in the first instance, lest convulsions or coma should supervene.

Case 1.—D. G., aged 7. The patient was involved, with many others, in an outbreak of food poisoning at an hotel. The remainder recovered after twenty-four hours or so, but this patient developed a temperature of 103° F. which persisted.

The child did not look seriously ill and, excluding the temperature, manifested no abnormality other than a suspicious brightness of the eyes and a definite tenderness in the left lumbar region.

Examination of the urine revealed pus cells in abundance and a pure culture of *Staphylococcus albus*.

The history of the case is suggestive. Some two months previous the tonsils had been removed on account of repeated attacks of tonsillitis. The child had complained periodically of pain in the back, which was accompanied by transient fever. These attacks had been attributed to "biliousness" and no professional opinion invited. The case was treated with urinary antiseptics; the temperature was subnormal on the fifth day. Within a fortnight the urine was free from staphylococci.

A second culture taken fifteen days later was negative, and the child, last seen eight months after the attack, had had no recurrence.

Case 2.—M. W., aged 5. Brought up for examination on account of a tendency to violent coughs and a general failure to progress.

The child had periodic attacks of severe tonsillitis with fever; the tonsillar glands were markedly enlarged and there was a chain of enlarged glands down the neck.

Early tonsillectomy was advised but postponed as the child was proceeding to England shortly.

The later history of the case was related by the mother. Shortly after arrival in England the child was seriously ill with persistent fever and pus in the urine. It was decided, after some days in which the disease steadily progressed, that it was hopeless to wait for any improvement before removing the tonsils, so tonsillectomy was performed. The tonsils were found to be deeply pocketed with pus.

The child eventually made a good recovery though the temperature and pus in the urine persisted for some time.

When seen by the writer in India some eight months later, the child was making good progress in every way, the urine was sterile and in other respects normal. Incidentally, the chain of enlarged glands had entirely subsided.

Case 3.—M. A., aged 4½ years. The child on first inspection appeared extremely ill; the temperature was 104° F., the pulse fluttering, and the patient vomiting and drowsy. There was a strong smell of acetone in the breath.

The urine, on examination, in addition to acetone, contained much pus and the presence of an abundant growth of *S. albus* was revealed on culture.

In this case there was not a very definite history of tonsillitis; it was impossible to see the tonsils, but there was slight enlargement of the tonsillar glands.

The child was treated for the first twenty-four hours with mixed alkalis and after that with urinary antiseptics.

The temperature was normal at the end of a week. Ten days after the onset of the disease the laboratory reported "very few colonies of *S. albus*". A fortnight later the urine was reported as sterile.

Case 4.—P. H., aged 6. Brought up for consultation on the grounds that the child was listless, restless, sweated at night, and had a capricious appetite. There had been several attacks of unexplained fever.

On physical examination no cause could be found except some carious teeth and slight evidence of intestinal dyspepsia. The tonsils were large but appeared clean. The urine revealed pus cells in abundance and a culture of *B. coli* was obtained.

The child was treated with alkalies and made good progress, but in January 1925 the urine, though free from *B. coli*, was stated to contain streptococci. This was possibly a contamination.

The original symptoms had disappeared after two courses of alkali treatment and the child appeared well save for some cardio-vascular irritability.

In May 1925 the patient developed acute tonsillitis with extensive purulent patches on the tonsils, was very ill and in an intensely toxic state. *S. albus* was reported in large numbers as a result of the throat swab culture and in small numbers in the urine within forty-eight hours of the onset of the disease.

In this case there was definite tenderness in the left lumbar region, marked cardio-vascular irritability and an intense acetone reaction in the urine.

The first treatment was directed to the throat, at the same time mixed alkalies were given to neutralise the acetone, and later urinary antiseptics were given.

The temperature came to normal after 8 days and the urine, examined after 17 days, was reported sterile.

The diagnosis of such cases rests on the consideration of inherent probabilities; tenderness in the lumbar region is not invariable. The examination of the urine, even by the naked eye, will often suggest the site of the lesion.

Treatment.—These are cases which will do much to restore the waverer's faith in the efficacy of drugs. The timely exhibition of antiseptics may be expected to produce tangible results within a very short time. The following mixture is recommended:—

Hexamine	..	grs. 3 to 5
Acid sodium phosphate	..	grs. 3 to 5
Sodium benzoate	..	grs. 3
Quinine acid hydrochloric	..	gr. 1
Aqua ad. $\frac{1}{2}$ oz.		

Four times a day, four hourly, and once in the night if the patient is awake.

The inclusion of quinine may call for criticism. Undoubtedly, if given in doses sufficient to secure an antiseptic concentration in the urine it is a powerful irritant to the kidney, but in small doses it is a diuretic and possibly adds its quota to the general antiseptic effect. Large quantities of fluid must be ingested.

The throat will, of course, call for special and careful treatment. Where patches are small and isolated, a mixture of equal parts of pure carbolic and camphor applied to the patches will accelerate their disappearance. The mixture, if heated during preparation, is not caustic.

Not the least important is the period of convalescence. It is held that the kidney is rendered susceptible to infections by slight trauma such as may be sustained in the vigorous movements of childhood. Bearing this in mind, it is clear that the patient must remain in bed for at least

ten days after the temperature has come down and the urine cleared.

Consideration of these cases raises the question as to whether it would not be wise, in all acute infections of the tonsils, to administer urinary antiseptics as a routine.

The offending tonsils must, of course, be removed as soon as the condition of the patient permits. It is well to remember that fatal cases of septicaemia—(the result of removing septic tonsils)—have been recorded, so time must be allowed for the subsidence of the infection and the development of some degree of immunity. The urine should be examined for recurrence every two months during the next year.

Finally, reasoning from analogy, it is for consideration whether the kidneys in acute exanthemata should not be treated with antiseptics in the hope that their involvement may be averted.

THE TRANSMISSION AND ETIOLOGY OF DENGUE: A CRITICAL REVIEW.

By ASA C. CHANDLER, M.S., Ph.D.

(Calcutta School of Tropical Medicine and Hygiene.)

IN a recent paper on the "Experimental Transmission of Dengue," by Siler, Hall and Hitchens (1925), which was reviewed and discussed by Megaw in the *Indian Medical Gazette* for August 1925, these authors come to the following conclusions:—(1) That the disease is readily transmitted by *Aedes aegypti* (*Stegomyia fasciata*), a confirmation of previous work by Cleland, Bradley and MacDonald (1918) in Australia, and by Chandler and Rice (1923) in America (the latter work was overlooked by the authors); (2) that the patient is infective for mosquitoes for at least three days after the onset of the disease; (3) that the virus requires at least eleven days for development in the mosquito before the latter can transmit the infection; (4) that mosquitoes which have once become infective remain so for long periods of time, probably throughout the remainder of their lives; (5) that *Culex fatigans* can be eliminated as a transmitter; and (6) that dengue produces a refractory state of more or less incomplete immunity which does not compare in permanence or solidity with that conferred by yellow fever.

This excellent piece of work leaves no room for doubt but that *Aedes* (*Stegomyia*) *aegypti* is a very ready transmitter of dengue. This fact had previously been fairly well established by Cleland, Bradley and MacDonald and by Chandler and Rice on smaller series of experimental cases, and by a large volume of epidemiological evidence collected by many different workers in many different places. The work of Graham (1903) and of Ashburn and Craig (1907) which seemed to incriminate *Culex fatigans* is based on inconclusive evidence. Graham having worked with mixed species of mosquitoes, and Ashburn and Craig having obtained only a single apparently successful

transmission which is not entirely above suspicion. Chandler and Rice (1923) came to the conclusion, from a considerable mass of epidemiological evidence; that in the Texas epidemic of 1922 *Culex fatigans* played at best a very minor part in the transmission of the disease, and considered it highly improbable that the epidemic would ever have developed in the absence of numerous *Aedes* (*Stegomyia*) *egypti*, although they were not prepared to say that *Culex* might not, under some circumstances, be capable of transmission. The negative transmission experiments of Siler *et al.* seem quite definitely to set aside this species as a transmitter. It does not follow, however, that *Aedes* (*Stegomyia*) *egypti* is the sole transmitter; it should be recalled that Koizumi, Yamaguchi and Tonomura (1917) in Japan reported successful experimental transmissions by means of *Aedes* (*Stegomyia*) *scutellaris* and *Armigeres* (or *Desvoidia*) *obturbans*, and considered the former species to be the principal transmitter in Formosa, where *egypti* is of such sporadic occurrence as to be a negligible factor. Both these species are closely related to *Aedes* (*Stegomyia*) *egypti*, and *scutellaris* has been suggested as a possible vector for yellow fever in the Orient if this disease should be introduced into its area. It is by no means improbable that other mosquitoes of the *Aedes* group may prove to be efficient transmitters of dengue, especially such species as *A.* (*Stegomyia*) *pseudoscutellaris*, which are habitual human feeders.

The specificity of disease organisms to particular species of insect transmitters is an interesting question. As a rule the specificity is not absolute, i.e., not a single species but a number of more or less closely related species are usually found to be capable of harbouring and transmitting a particular virus. The ability of the virus to exist or undergo development in an insect vector is by no means the only factor which comes into consideration; the food habits of the insects may also be of great importance. Some *Anopheles*, for instance, which have been shown to be good nurses for malaria parasites experimentally are of no practical importance as malaria transmitters in nature, because they do not frequent human habitations and do not habitually feed on man. It is quite possible in the case of some disease germs that contact with non-human blood in an insect's digestive tract would prove injurious, thus limiting effective transmission to insects which habitually feed on human beings and to individuals which had not fed on non-human blood between the time of an infective meal and a subsequent potential transmitting bite. We know that pathogenicity of organisms may be altered by passage through different kinds of host animals, and it is possible that mere exposure to the blood of different host animals in an insect vector may have a similar effect. There is, in fact, some reason to believe that in some cases the insect

may serve as a sort of training camp for organisms of non-human origin where exposure to human blood under modified conditions may increase their tolerance to such an extent as to render human infection possible. Such a hypothesis may very well account for the origin of *Trypanosoma rhodesiense* and for the peculiar distribution of Chagas' disease in South America as compared with the distribution of *Trypanosoma cruzi*-like organisms (see Chandler, 1923).

Yellow fever stands out as an instance of a disease with a highly specific insect vector. But it is by no means certain that *Aedes* (*Stegomyia*) *egypti* is the sole possible transmitter of the disease. It happens that no other closely related mosquito (i.e., of the *Stegomyia* or *Armigeres* groups) which is common and habitually feeds on human beings occurs in the Western Hemisphere, hence transmission of yellow fever there is limited to the single available species. In West Africa *egypti* is the predominant species of its group, although *sugens* and *africana* both occur there; but I have been able to find no reference to any work which would indicate whether or not these species might also transmit the disease. If yellow fever should be introduced into the habitats of *scutellaris* and *pseudoscutellaris* in the Orient, which are very closely related to *egypti* and have similar habits, the writer ventures the opinion that these species, as well as *egypti* would have to be dealt with as transmitters of yellow fever.

The fact that dengue and yellow fever have been shown to be transmitted by the same group of insects does not necessarily indicate any close relationship between their respective viruses, any more than the transmission of Oriental sore and sandfly fever by *Phlebotomi*, or of typhus and relapsing fever by body lice indicate a relationship of the causative organisms of these diseases. Chandler and Rice (1923) have called attention to a number of significant differences between dengue and yellow fever and expressed the opinion that the supposed relationship of the two diseases has been over-emphasized. The finding of *Leptospira icteroides* in yellow fever and the failure of most workers to find a similar organism in dengue (see for example Chandler and Rice, 1923 and Knowles and Das Gupta, 1924) throws still further doubt on the relationship of the diseases in spite of their similar transmitters. Couvy (1921) found scanty spirochaetes in the blood of a supposed dengue case two to three hours before the onset of the fever, and in 1922 reported the finding of spirochaetes both before and for 3 to 48 hours after the onset of fever in cases recorded as dengue but which appear not to be dengue but sandfly fever. De Faria (1923) records scanty spirochaetes in a single film taken from a dengue patient soon after the onset of fever, but in view of the observations of Knowles and Das Gupta (1924) on "pseudospirochaetes" in dengue blood, objects

which also puzzled the writer for some time but which were found to be due to fibrin, this observation must be accepted with some hesitancy. Whittingham (1922) records the isolation of spirochaetes in culture from 6 out of 26 cases of sandfly fever in Malta, but inoculation of the cultures into non-immunes failed to reproduce the disease; moreover, as Megaw has pointed out, it is doubtful whether Whittingham's cases were uncomplicated sandfly fever.

This brings up the question of the relation of dengue and sandfly fever, a point which Megaw (1923) has ably discussed. Clinically the diseases certainly overlap. It is not unlikely that the two diseases have closely related causative organisms, and it is even possible that the same virus may be involved, modified in its pathogenicity by development in mosquitoes on the one hand and in sandflies on the other. Couvy's observations in Syria lend some support to this view.

There is one important conclusion reached by Siler, Hall and Hitchens which must be accepted with reservations. Their view that the dengue virus requires eleven days or more for development in the mosquito before transmission can occur, based on three cases in which bites of infected mosquitoes failed to produce disease before eleven days' incubation but succeeded later, and on an unstated number of unsuccessful transmission experiments prior to an incubation of eleven days, is at variance with results obtained by Chandler and Rice, and also with epidemiological evidence. Chandler and Rice succeeded in transmitting the disease in 4 out of 6 cases with mosquitoes which had been infected 24, 48, 72, and 96 hours previously on patients in the first to fifth days of the disease; the human incubation period in these experimental cases varied from a little over 4 days to 6½ days. Every precaution was taken to prevent infection from outside sources, and the mosquitoes were laboratory bred. There is, of course, the possibility that infected mosquitoes were used for breeding purposes and that the virus is capable of transmission to the offspring of such infected mosquitoes. The results of Chandler and Rice are more in accord with the known epidemiology of the disease than are those of Siler *et al.* The rapidity of the spread of the disease is one of the outstanding features of dengue, and is hardly compatible with a necessary eleven-day incubation period in the transmitting agents, which would result in a much slower spread both on account of the time required for the mosquito to become infective and on account of the mortality of infected mosquitoes between the time of feeding on an infected individual and the development of infectivity. The conclusions reached by Siler *et al.* would certainly appear to be justified by the results obtained by them, and I am at a loss to explain the difference between their results and ours unless, as suggested above, congenital infection

of mosquitoes can occur. It is unfortunate that the previous work of Chandler and Rice was overlooked by the workers in the Philippines, since it might have suggested to them possible reasons for their failure to get transmission in shorter periods of time, and experiments to throw further light on the subject.

SOIL ACIDITY AND SURVIVAL OF HOOKWORM LARVÆ.

By ASA C. CHANDLER, M.S., Ph.D.

(Hookworm Research Laboratory, Endowed by the Indian Jute Mills Association, Calcutta School of Tropical Medicine and Hygiene.)

It is a prevalent opinion that acidity in soil has a tendency to shorten the life of infective hookworm larvæ, Hirst (1924), for instance, says "a markedly acid reaction is also most unfavourable to the continued survival of hookworm larvæ." and remarks that the most favourable pH reaction for the development of the larvæ in cultures from faeces requires investigation.

The fact that hookworm disease thrives on tea gardens where the soil has a markedly acid reaction, averaging about pH 5.5, led me to doubt whether, within the pH range of ordinary agricultural soils, the reaction had any marked effect on the survival of hookworm larvæ. The well known resistance of hookworm larvæ to weak chemical solutions,

and the lesser extent to which larvæ, living on the surface of soil, would be exposed to the injurious effect of acidity than would be the case when immersed in solutions, added weight to the doubt. The fact that immersion of infective hookworm larvæ even in a N/10 solution of hydrochloric acid failed to kill them in 18 hours when the temperature did not exceed 75°F., also suggested that the larvæ were not highly susceptible to acidity.

In order to test this point, four samples of soil with varying hydrogen-ion concentrations were placed in small galvanised iron tumbler-like receptacles, holding about 100 c.c. each. Six receptacles of each type of soil were placed respectively in four large pudding pans on a bed of cotton-wool, which was kept saturated with neutral distilled water. Holes were punched in the bottoms of the receptacles so that the soil contained in them could be kept moist by absorption of water from the bed of wet cotton-wool. Soils 1 to 3 were tea garden soils kindly sent to us by the Toklai Experiment Station in Assam. Soil No. 1 was an unaltered red clayey tea soil the pH concentration of which during the course of the experiment, tested by a colorimetric method each time that a sample was used for extraction of larvæ, varied from pH 5.2 to pH 6; soil No. 2 was a similar soil which had been treated with lime and had a pH which varied from 5.6 to 7; soil No. 3 was a similar soil which had been more heavily

same lot, freshly extracted from a 7-day old charcoal culture. Unfortunately the patient from whom the larvæ were obtained absconded after the experiment was started and before treatment could be given to determine whether the larvæ were those of *Necator*, *Ancylostoma* or both. The receptacles were kept uncovered in the laboratory, where the maximum daily temperatures usually ranged between 85°F. and 95°F. One receptacle from each group was examined for hookworm larvæ at intervals of two weeks until no more larvæ could be found, by placing the upper one inch of soil in a Bærmann apparatus for extraction of hookworm larvæ. A portion of the remaining deeper layer of soil was used for determining the hydrogen-ion concentration. The method employed was as follows:—To 12 gms. of moist soil was added 8 c.c. of neutral distilled water and the mixture poured into a collodion sac. The sac was immersed in a tube of slightly larger diameter containing about 12 c.c. of neutral distilled water. After dialyzing for one hour the sac was removed and the water in the tube tested for its pH concentration by a colorimetric method, brom-thymol-blue and methyl-red being used as indicators. All glassware used was boiled in acid shortly before being used in order to do away with alkalinity from the glass.

The results of the experiment are shown in the following table:—

Date.	Soil No. 1.		Soil No. 2.		Soil No. 3.		Soil No. 4.	
	Hookworm larvæ.	pH.	Hookworm larvæ.	pH.	Hookworm larvæ.	pH.	Hookworm larvæ.	pH.
10th April, 1925	2,000	6	2,000	6.7	2,000	6.9	2,000	7.2
24th "	1,168	6	1,250	7	835	7.2	1,170	7.45
11th May, 1925	1,200	5.5	350	6	350	6.4	3*	7.3
1st June, 1925	103	5.7	27	6.3	384	6.7	128	7.
17th "	413	5.2	73	5.6	286	6.3	155	7.4
1st July, 1925	2	6	6	7.1	45	6.1		7.5
15th "	0	6	0	7.1	0	6.8	dried	..

* The soil in this receptacle became partially dry about two weeks previously.

treated with lime and had a pH varying from 6.1 to 6.7; soil No. 4 was a dark-coloured loamy soil obtained from the Calcutta Zoological Garden having a pH varying from 7.1 to 7.5. The cause for the different pH values for different samples of the same soil is not known, but may have been due to varying amounts of absorption of CO₂ or other gases from the atmosphere. On the surface of the soil in each receptacle there were placed approximately 2,000 larvæ on 10th April, 1925, at the height of the hottest weather in Calcutta. These larvæ were all of the

It was found to be difficult to keep an even degree of moisture in the receptacles, and it is probable that the variable results are due to a large extent to this factor. The receptacle from No. 4 examined on 11th May, 1925, for instance, had been noted as having partially dried. In general, however, it will be noticed that the reduction in numbers of larvæ took place at a rapid rate in all the soils, being reduced to an average of about 10 per cent. of the original number in 68 days and to about 0.3 per cent. in 81 days, while at the end of 96 days no more larvæ could be extracted.

Making allowances for the individual differences in the receptacles it is evident that no appreciable difference in time of survival can be observed corresponding to differences in acidity of the soil, although in so far as the figures are sufficient to indicate any difference, the difference is in favour of the more acid soils. A very striking difference in the soil nematode population of the different soils was observed, these becoming progressively more numerous in soil No. 1 until, on the last date of examination, an enormous number, certainly many thousands, were extracted. No progressive increase in soil nematodes was observed in the other samples.

It would appear, therefore, that the acidity likely to be present in ordinary agricultural soils, at least up to a hydrogen-ion concentration of 5.5, does not interfere with the survival of hookworm larvæ.

A NOTE ON THE TOXIC SYMPTOMS OF ORGANIC ARSENIC.

By A. DENHAM WHITE, M.B., B.S., F.R.C.S. (Edin.),
LIEUTENANT-COLONEL, I.M.S.,

*Superintendent of the Voluntary Venereal Hospital,
Alipur, Calcutta, and Civil Surgeon, 24-Parganas,
and*

RAI SAHIB SITAL CHANDRA DUTT,
*Medical Officer and Deputy Superintendent,
Voluntary Venereal Hospital, Alipur, Calcutta.*

THE treatment of syphilis has of late years tended more and more to resolve itself into a course of intravenous injections of one or other of the numerous preparations of organic arsenic, combined with mercurial medication or not as the case may be. So general has the treatment become and so dramatic the early results that the public has come to regard the giving of an intravenous injection as being far simpler and more convenient than taking a dose of medicine, and the practitioner, having acquired a certain manipulative dexterity, approaches it in much the same spirit. The following three cases, occurring in a series of 3,098 injections of organic arsenic extending over three years, shew that the procedure is not unattended with a definite risk of alarming sequelæ. It is a risk, moreover, of which we have no warning, for in the present state of our knowledge there is no method of estimating the tolerance of any particular individual to the drug.

Case 1.—A Hindu female, aged 24, was admitted into the Voluntary Venereal Hospital on 22nd March, 1925, suffering from a very generalised secondary syphilide. The eruption was of a maculo-papular character and

extended all over the trunk and limbs, involving both flexor and extensor surfaces and the palmar aspects of both hands. Her general health was good and her nutrition fair. There was no lesion on the genitalia and the urine contained no albumen.

The blood was examined on admission by both the Wassermann and Sachs-Georgi tests and in both a strongly positive result was obtained.

Hospital records showed that she had been admitted two years previously in an advanced state of pregnancy, suffering from hard chancre and gonorrhœa. The Wassermann reaction was at that time also strongly positive. She however then refused to have any injections and was therefore treated with mercury, etc. She was delivered of a male child in hospital which survived with the loss of one eye from ophthalmia.

She had the first injection consisting of 0.3 gm. novarsenobillon on 31st March, 1925; this was followed in half an hour by a rise of temperature to 100°F. and by a rigor accompanied by headache and nausea. These symptoms however passed off within 24 hours.

The second injection was given on 7th April, 1925. The same dose was given and was followed as before by a rise of temperature to 101°F. and a rigor; all symptoms passing off within 48 hours as on the previous occasion.

The following morning, i.e., the third day after injection, she again complained of headache, nausea and anorexia. The tongue was moist but furred; pupils slightly dilated; the urine was scanty but contained no albumen, and there was no rise of temperature. Adrenalin was administered at once. By the evening however she had become semi-conscious, though responding to stimulus and exhibiting irritability. The pulse was full and compressible, the tongue coated, the pupils dilated and the neck slightly rigid. Four ounces of urine were drawn off by catheter.

By the following morning coma had deepened, the pulse was full and irregular, the extremities and neck were rigid, and the jaws clenched. Well-marked epileptiform convulsions occurred during the day, but there was still a response to painful stimuli. Coma however continued to increase in spite of repeated injections of adrenalin, and muscular rigidity became still more marked. At this stage venesection was performed without any relief, and the patient died during the night, about 100 hours after the second injection.

Case 2.—A Hindu female, aged 22, was admitted into hospital on 9th December, 1922, with a mixed infection, having a hard chancre of two weeks' duration with a profuse gonorrhœal discharge. There were no cutaneous lesions and the Wassermann reaction was strongly positive.

The first injection, consisting of 0.45 gm. novarsenobillon, was given on 25th December, 1922, and was followed by headache and vomiting, but there was no rise of temperature or rigor.

On 5th January, 1923, i.e., 11 days after injection, she was seized with epileptiform fits following one another without any return to consciousness and remained in the "status epilepticus" throughout the day, making no response to stimuli. There was rigidity of the neck muscles and difficulty in swallowing; the pupils were normal. The "status epilepticus" persisted for nearly 24 hours with muscular twitchings, and there was no response to painful stimuli. The urine was drawn off but contained no albumen. Repeated doses of adrenalin were administered and by the evening of 7th January, 1923, she showed signs of returning consciousness. Convulsions had ceased but the dejecta were still passed in the bed. The next morning she could talk and sensation had returned. Improvement slowly continued throughout the next three days but prostration was marked. One week after the injection she had sufficiently recovered for her relatives to remove her from hospital and all trace of her has since been lost.

Case 3.—A Hindu female, aged 24, was admitted into hospital suffering from primary syphilis on 4th October, 1920. She at first underwent a short course of

mercurial treatment but later expressed her willingness to have a course of injections and accordingly started on 21st October, 1920, with 0.45 gm. novarsenobillon, followed on 1st November, 1920 by 0.6 gm. and on 18th November, 1920 by 0.9 gm., making a total of 1.95 gm. Her local lesions had by this time completely disappeared and her general health much improved. On 8th December, 1920, i.e., 20 days after the last injection, she developed jaundice which rapidly increased, accompanied by fever. Her condition became steadily worse till 18th December, 1920, when she commenced to have epileptiform convulsions which passed on to the "status epilepticus" and died on 20th December, 1920.

The treatment employed in this case, as in the other cases, consisted mainly in the injection of adrenalin.

The similarity of symptoms in Cases 1 and 2 is sufficiently marked to suggest a common cause coming into action at varying periods in the two cases, while the variation of jaundice in the third case differentiates it from the other two.

The train of symptoms exhibited by Cases 1 and 2 are spoken of by McDonagh as pseudotoxic, appearing on the third day after injection and are otherwise described as "reactionary inflammation" or the "Jarish-Herxheimer reaction." In every such case, the patient has, or has had, generalised syphilis and such symptoms never occur in the primary stage. The cases fall into two main classes, intracranial and visceral; the cases quoted being of the former variety. The lesion appears to be a hæmorrhagic encephalitis and is assumed to be due to the battle going on between the colloidal protein particles and the active phases of the organism. The remedy intensifies the engagement in which the host assists by a dilatation of the capillaries of the area involved, in order that more protein particles may be brought into the field. The dilatation results in a raising of the intracranial pressure with the sequence that certain nerves are pressed upon and the patient becomes comatose and dies.

As in Case 1 a post-mortem was not allowed we are unable to confirm the presence of hæmorrhagic encephalitis, but in other respects it conforms to McDonagh's description.

In the second case symptoms came on on the 11th day after injection, a delay that is not easy to reconcile with the theory put forward by McDonagh.

Case 3, which came under the observation of one of us (S. C. D.), appears to have been one of true arsenical hepatitis, passing into acute yellow atrophy with the fatal result that always attends this condition. In this case the probabilities are that the disease had not become generalised, and therefore the jaundice was not of syphilitic origin but was primarily toxic. Unfortunately there is no record in the notes as to whether leucin and

tyrosin were present in the urine neither was a post-mortem obtainable. The case, however, so nearly corresponds with the clinical picture of acute yellow atrophy that we think we are justified in attributing the death to that cause.

The undoubted benefits of adrenalin in the treatment of these so-called nitritoid crises has been dealt with by Ehrlich who expressed the belief that untoward symptoms are due to a deficiency in the secretion of adrenalin. Brown and Pearce have shown that arsenic has a selective action on the adrenals and Hirano has shown that there is a marked deficiency in the epinephric content of the blood and the gland itself after an injection of organic arsenic even in therapeutic doses.

Millian considers that the symptoms are due to a serous exudate following a vasodilatation in the cerebral vessels, causing cerebral manifestations varying in severity from headache to convulsions. He also concludes that there must be some intimate connection between arsenobenzol and the suprarenals. Experiments have shown that after the administration there is a sudden consumption of adrenalin in the circulating blood, and the glands may be unable to make up the supply. The following facts support this theory of the cause of these nitritoid crises:—

1. The symptoms may be averted by the use of adrenalin.
2. The blood serum of animals injected with novarsenobenzol contains a smaller quantity of vasi-contractile substance than does normal serum.
3. The adrenalin content of the suprarenals diminishes after the administration of arsenobenzol.

Of the various theories put forward to account for the occurrence of these nitritoid crises, it seems that the adrenalin theory has a certain clinical support in the benefit derived from the administration of adrenalin. One of us (A. D. W.) recently saw a case of syphilitic myocarditis occurring in an untreated case six months after infection. A minimum dose of sulfarsenol was given subcutaneously and was followed in 24 hours by a typical nitritoid crisis manifested by very severe convulsions, coma and peristaltic inhibition. Adrenalin 1 in 1000 in 10 minim doses was given subcutaneously every 4 hours with almost immediate relief and ultimate recovery in a case that appeared almost hopeless.

Our reason for the publication of these cases is, firstly, to remind our fellow practitioners that there is this ever-present risk in the use of organic arsenic, and, secondly, to draw attention to the remedy available in the use of adrenalin.

STIBOSAN (VON HEYDEN "471").

By L. E. NAPIER, M.R.C.S., L.R.C.P.,

Kala-Azar Research Worker (Indian Tea Association Endowment), Calcutta School of Tropical Medicine and Hygiene.

I AM repeatedly receiving letters from practitioners asking various questions with regard to the use of Stibosan (von Heyden "471"). Although in most instances I have managed to find time to answer these letters I feel that the few details which are given below might save me much letter writing in the future.

Stibosan, the sodium salt of meta-chlor-para-acetyl-amino-phenyl stibinic acid, was first introduced for the treatment of kala-azar by me at the School of Tropical Medicine about two years ago and the first report was published in this journal in December 1923. Since then the compound has been used in a large number of cases and the good opinion that I formed of it has been confirmed by my subsequent experience.

A report of my total experience up to the end of March 1925 is in preparation and will be published shortly. Very favourable reports of its value in the treatment of kala-azar have also been made by other observers, including Sir Leonard Rogers (*Medical Annual*) and Lieutenant-Colonel E. D. W. Greig, I.M.S. (*Indian Journal of Medical Research*). It is only however during this year that the compound has been obtainable on the market.

It is now obtainable from most druggists in sealed ampoules containing either 0.2 or 0.3 grammes.

The Solution.—The required dose should be dissolved in sterile distilled water in order to make a 5 per cent. solution, i.e., 0.05 gramme will require 1 c.c., 0.1 gramme 2 c.c., 0.2 gramme 4 c.c., and 0.3 gramme 6 c.c. The solution should *not* be boiled and should be prepared freshly. (We have used solutions that have been kept 48 and even 72 hours without any ill-effects but as there is danger of the solution becoming contaminated, if kept, it is advisable to prepare the solution each day.)

DOSAGE.

Adults.—Comparatively strong adults can be given 0.2 gramme as the initial dose and 0.3 gramme subsequently. More debilitated ones can be given 0.15 gramme as the initial dose and 0.25 subsequently and very debilitated patients should be given 0.05 gramme as the initial dose, subsequent doses being increased cautiously.

Children.—Children tolerate the preparation in relatively larger doses. At the age of 3 years a maximum dose of 0.1 gramme, at the age of 9 0.2 gramme and from 12 years upwards a maximum dose of 0.25 will be well tolerated. The initial dose should be about half the maximum dose.

Intramuscular injections.—In children aged between 1 and 2 years I have given up to 0.1 gramme intramuscularly without causing more than slight local pain.

Total dosage.—A total of about 3 grammes of Stibosan for an adult weighing 100 lbs. is a little above the average "sterilising" dose. Cases that have previously shown any signs of resistance to treatment should be given a more prolonged course. Adults weighing less than 100 lbs. and children require proportionately less.

The routine course of injections will thus be from 11 to 15 injections. These should be given twice or three times weekly.

CONTRA-INDICATIONS.

There are few contra-indications to the use of Stibosan in kala-azar. There does not appear to be any danger in giving the compound to patients suffering from chest complications, as is the case with certain other antimony preparations. Neither a trace of albumen in the urine nor diarrhoea need be considered as signals to withhold treatment.

A certain percentage of cases of kala-azar under treatment with any form of antimony will develop jaundice; if this occurs it is as well to discontinue the injections for a short time until the jaundice shows signs of improvement, after this the treatment can be continued without danger of the jaundice relapsing.

In cases that show a certain amount of oedema of the feet, or develop this during treatment, the treatment can be given without any danger but my results have not been good with cases that have shown definite ascites. Thus definite ascites should be considered as a contra-indication.

SPECIAL ADVANTAGES.

In common with other pentavalent preparations of antimony (e.g., urea-stibamine) this compound makes it possible to effect a complete cure in about 12 injections instead of the 30 to 40 which were usually necessary with the antimony tartrates. The severe febrile reaction, the distressing coughing and the vomiting which are such common sequelæ of intravenous injection of the tartrate solutions are practically unknown when Stibosan is used.

This preparation has special advantages over the other pentavalent preparations in that it is a definite compound; it will therefore be of constant composition; and it is very stable. It does not undergo any change when in contact with the air. It is supplied in sealed ampoules but it is not essential that the compound should be used on the day the ampoule is opened. Thus, when a child is being treated, an ampoule of 0.2 gramme can be divided into three doses of 0.05, 0.05 and 0.1 grammes. An additional advantage is that when a large number of cases are being treated, as is the case in a hospital, 2 grammes, 3 grammes or whatever the amount required for the day can be weighed out (from

the 10 grammes bottles which are supplied for hospital use) and dissolved. The labour of opening each ampoule is thus avoided.

I have retained a portion of my first sample and quite recently I was able to show that it had neither undergone any chemical change nor increased in toxicity although it had been kept in an ill-corked bottle for 2 years at the ordinary Calcutta room temperature.

IZAL IN CHOLERA.

By LALBEHARY GANGULY,

Teacher In-Charge of the Cholera Ward, Campbell Hospital, Calcutta.

To test the efficacy of izal in the treatment of cholera it has been given a fairly extensive trial in the Cholera Ward of the Campbell Hospital from January to May 1925. As outbreaks vary in severity, to compare the effect of izal with that of our usual treatment with calomel, we put cases on izal or calomel, alternately, as they were admitted. Although the advocates of the izal treatment consider saline transfusions unnecessary, in view of the fact that practically all our cases were totally pulseless on admission, we did not consider it safe to withhold saline transfusions in any cases. If izal had any good effect it should manifest itself in a higher recovery rate even though cases received transfusions.

Izal was given on the lines recommended (Palmer 1924). Calomel was given in fractional doses until the stools changed colour. In both groups saline transfusions were given according to specific gravity indications of the blood. Calomel cases received alkalies with saline transfusions when necessary but izal cases did not (except by the mouth in some as noted below), this apparently being considered unnecessary with izal.

From January to May, 513 genuine cases of cholera were dealt with.

The mortality amongst calomel cases was 22.5 per cent.

The mortality amongst izal cases was 23.6 per cent.

The mortality is practically the same in the two cases but it should be noted that directly any one of the cases put on izal showed signs of impending uræmia, alkalies were started by the mouth and if there was no improvement within about twelve hours, izal was stopped altogether and alkalies pushed both intravenously and by the mouth. Thus in 23 cases it was considered imperatively necessary to stop izal and give alkalies. Taking these 23 as deaths, mortality in the izal group would stand at 35 per cent. much higher than in cases treated without izal. It is recognised that cresol bodies irritate the kidneys, and their administration in cholera would naturally be conducive to the onset of uræmia. It is a matter for some surprise that uræmia was

not more frequent in the izal group than was actually the case. This is probably because absorption from the gastro-intestinal tract is minimal in cholera.

Other complications of cholera, such as bronchopneumonia (this exacted a heavy toll), asthenia, parotitis, etc., were practically the same in each group.

The number and amount of saline transfusions were also practically the same.

Change in the character of the stools was somewhat earlier in the calomel group. Vomiting was the same in both. Vibrios were recovered from the stools with equal frequency in the two groups. It was not possible to investigate as to whether izal cases became vibrio-free earlier than calomel cases.

CONCLUSIONS.

(a) In the treatment of cholera, izal cannot be put on a higher level than any other drug so far tried.

(b) It is at a distinct disadvantage compared with others that have no irritant action on the kidneys. So far as any specific action is concerned, there is not much to choose between any of the drugs in common use *provided the drug exhibited has no irritant action on the kidneys.*

(c) Success, of the standard of an 80 per cent. recovery amongst pulseless cases, lies in judicious administration of salines and alkalies.

LICHEN SPINULOSUS.

By GANAPATI PANJA, M.B.,

Assistant Professor of Bacteriology, Calcutta School of Tropical Medicine and Hygiene.

We have come across four cases of this condition—one a young girl and the others male adults; two belonging to the better class and the rest to the lower class; one fair complexioned and the others dark.

The disease came on spontaneously but in the case of the first it appeared some time after typhoid. The general health of all was good. There were no septic foci in their teeth, throats, or elsewhere. There was no family history of the disease and no history of syphilis. The duration of the disease varied from three months to a year. No spontaneous cures and relapses were noticed.

The disease is characterised by more or less symmetrically distributed groups or patches of sago-grain-like papules surmounted by filiform spines, arising from the hair follicles and situated most commonly on the abdomen and on the back of the shoulders near the axillæ. A distinctly rough feeling is experienced by passing the hand over the lesions. The appearance may

be compared to the characteristic arrangement of staphylococci under a microscope. No subjective symptoms are present.

Pathology.—A section of the lesion shows cellular hypertrophy around the hair follicles. No organisms could be detected. Most of the books on skin diseases state that the cause of the disease is at present unknown, but I have found fungi of the *tinca* group in scrapings from all the cases. The examination was made as follows:—

Horny plugs were scraped with a knife, treated with liquor potassæ (B.P.) on a slide and covered with a vaselined cover-glass. About 1 to 2 hours later the cover-glass is pressed a little so as to flatten the plugs and an examination is made with the 1/6th lens. The

*Fungi seen in scrapings from
L. spinulosus.*

accompanying diagram shows the appearance of the fungi. The keratin of stratum corneum swells up when treated with liquor potassæ and assumes a fungus-like appearance but this is quite different from the appearance of the true fungi.

Attempts have been made to grow this fungus, so far without success. We are waiting for further cases and if fungi are found in every case or at least in a large number of them, then,

the name *lichen spinulosus* may be omitted and replaced by *tinca spinulosus*.

The disease has to be distinguished from the following:—

- (1) *Lichen planus*.
- (2) *Keratosis pilaris*.
- (3) *Pityriasis rubra pilaris*.

Lichen planus is an irritable disease and the papules are flat, glistening and polygonal in shape.

In *keratosis pilaris* the lesions are usually present on the extensor aspects of arms and thighs and not grouped in patches.

Pityriasis rubra pilaris is an inflammatory disease and shows scaliness.

Treatment.—McLeod says that the affection is comparatively easily cured, but we hold just an opposite view. We have tried strong keratolytic remedies without rapid improvement. Vigorous scrubbing with soap, rectified spirit and hot water, and applications of tincture of iodine 4 drs., liq. hyd. perchlor. 1 dr., aqua ad. 1 oz. followed by ung. acidi salicylici 1 dr. to 1 oz. at night have been found the most successful. If iodine irritates, its application should be stopped. Painting single patches with diluted trichloroacetic acid may do good. Sometimes resorcin and benzoin lotion are useful. We have not tried the effects of x-rays on the disease.

FUNGO-SPIROCHÆTAL AFFECTIONS OF RESPIRATORY PASSAGES.

By DR. SARUP NARAYAN MATHUR, L.M. & S.,

Civil Surgeon, Unao, Oudh,

and

K. N. ZUTSHI, M.B., B.S.,

Honorary Clinical Pathologist, Civil Hospital, Unao.

WHILE examining sputum of cases for T.B. at the Unao Hospital Laboratory, we have come across forms closely resembling the *Monilia tropicalis* of Castellani, together with spirochaetes, pneumococci and *Micrococcus catarrhalis*. In a few there were staphylococci, streptococci and seldom fusiform bacilli.

The first case we saw in 1923 was a female of a well-to-do family and the appearance of *Monilia* reminded us of the articles published in the *Indian Medical Gazette* for November 1922 and April 1923, and so we began to examine the sputum of all suspected cases.

Up to this time we have come across 8 such cases (5 males and 3 females), and they can be classified into the following types:—

(1) Chronic cough with involvement of tonsils, sometimes with fever for two or three days and sometimes bloody sputum. Such cases were otherwise apparently healthy.

(2) Acute febrile bronchitis with bloody sputum supervening on sub-acute throat trouble. Acute condition disappearing rapidly after the use of the pot. iodide and

creosote mixture but Monilia, although decreased, were still to be found.

(3) Chronic bronchitis trouble with hectic or off-and-on fever, pain in the chest and back and sometimes bronchitic symptoms with abundant morning or evening sputum like boiled sago grains. Such cases were much run down in health.

(4) Chronic involvement of lungs, clinically of generalised tuberculosis showing apical consolidation, crackling and crepitant râles all over, much emaciation and fever, and large quantity of muco-purulent sputum.

Our first case was practically cured by autovaccine therapy and improved much in health except that there remained only a non-productive cough of throat origin. For more than a year now she has enjoyed apparently good health.

Another patient who agreed to have autovaccine treatment has been much relieved but is still under treatment. His treatment began in the beginning of this year.

The rest either did not agree to have the treatment suggested to them or having had little trouble except chronic tonsillitis and pharyngitis, were satisfied with the ordinary treatment. No patient up to the time of writing has been worse except one whom we expected to do badly as we saw him in a very advanced condition, classed in (4). He was asked to stay in hospital but he never returned from his village. Our experience is quite contrary to the cases described in the *Indian Medical Gazette*, where all the cases proved fatal.

MICROSCOPICAL APPEARANCES AND STAINING REACTIONS.

The fungus represents a thalamus with numerous hyphæ projecting from it and bunches of sporangia lying in the vicinity and between the Monilial threads.

Under 1-12th oil immersion lens, the hyphæ are medium chains about 40 μ long, but sometimes much longer. They show square-ended rods lying end to end, separated by a small interval. Each rod sometimes shows at either end a granule more darkly stained than the rest of the body.

Sometimes we find bunches of thinner and shorter Monilia, but we have never been able to see such forms projecting out of the thalami.

They stain well with ordinary dyes and are non acid-fast. The spirochætes show short and long, thick and thin, forms with tapering ends and the number of spirals varies from 2 to 8. They are stained well with dilute carbol-fuchsin.

Having no appliances for incubating and differentiating the various species of Monilia and spirochætes, we are handicapped in committing ourselves on such cases but that

they were thoroughly and repeatedly examined and watched all through the treatment. Hence, we can surmise that they were cases of fungus and spirochætal diseases of respiratory passages clinically.

A SUMMARY OF THE RESULTS OF AUTOPSIES HELD AT THE CALCUTTA POLICE MORGUE DURING 1923-1924 ON CASES OF SUDDEN DEATH.

NOTES.

In cases of poisoning there is usually not much information to be obtained and it is difficult to classify poisoning as to whether accidental or suicidal.

Suicide by burning is comparatively common in Hindu females; out of 26 such cases, 24 were Hindu females, 1 an Indian Christian, and 1 a Hindu male.

Suicide by hanging. Out of 20 such cases, 9 were Hindu females, 8 Hindu males, and 3 Mahomedan males. These were the only 3 cases of suicide amongst Mahomedans.

Suicide by gunshot wounds. Three were European males and 2 were Hindu males, one of these was a sepoy who running amok and shooting a havildar, finally shot himself.

Opium is the commonest poison to be used for suicide and probably many of the cases classified as accidental, due to an overdose, were in reality cases of suicide.

One case of carbon monoxide gas poisoning is interesting in that there were 3 persons in the room that night, father, mother and child; of these the mother died, the father was unconscious, and the child apparently was unaffected.

A case of poisoning by liquid extract of nuxvomica, which was accidentally dispensed in mistake for liquid extract of ergot, occurred in a European female. The dose said to have been given was 30 minims which contains about $2\frac{1}{5}$ ths of a grain of strychnine, i.e., less than $\frac{1}{2}$ gr., the known fatal poisonous dose; but of nuxvomica itself the smallest known fatal dose is 30 grs. of the powder, equivalent to $1\frac{1}{3}$ gr. of strychnine only, so that probably 30 minims of the liquid extract may be a fatal dose.

A Mirror of Hospital Practice.

A CASE OF ECHIS CARINATUS (?) POISONING.

FAILURE OF CALCIUM AS A THERAPEUTIC AGENT. DEATH IN 86½ HOURS.

By F. WALL, C.M.G., K.H.S.,
COLONEL, I.M.S. (RETD.),
Maymyo, Burma.

THE following interesting case of ophitoxæmia occurred in Karachi when I was Assistant Director of Medical Services in that district. The case came under the care of Major Newton Davis, I.M.S., to whom I am indebted for these notes.

I append an abridged version of the notes on the case sheet.

History.—Babu Kale, a sepoy in the 2½th Mahratta Light Infantry, aged 23, reported sick at 8 A.M. on the 18th of August, 1923, at the Indian Station Hospital, Karachi. He had a swollen foot which he said was due to a fall. He was selected for x-ray examination and admitted into hospital. At 9-30 A.M. he confessed that he was bitten by a snake at about 5 A.M. whilst going to the latrine and did not report this at first on account of fear. The snake had not been killed and had escaped.

Present condition.—Examination revealed two tiny punctures on the dorsum of the left foot which was very swollen. The patient complained of severe burning pain in the foot and faintness. His pulse was fairly good and respiration normal.

A tourniquet was applied, the punctures incised and potassium permanganate crystals were rubbed in. Antivenene, 40 c.c., was administered intravenously.

At 2-30 P.M. the patient was very restless. He was bleeding freely from the gums and expectorating blood. The dressings on the foot had been changed three times since the morning owing to soakage of blood. Pulse, very feeble. 15 minims of adrenalin hydrochloride, followed by 30 c.c. of antivenene, were injected subcutaneously.

At 7 P.M. his pulse was still very feeble and bleeding continued. $1\frac{1}{60}$ th grain of strychnine was injected subcutaneously.

At 7-30 P.M. there was no improvement. A 1 c.c. ampoule of pituitrin, followed by 15 minims of adrenalin chloride, was injected as well as $1\frac{1}{2}$ grs. of calcium lactate in 5 c.c. of saline solution intramuscularly.

At 11 P.M. he was in the same state. A second dose of pituitrin was injected.

At 5 A.M. on 19th August, 1923, the patient was in the same state. 1 c.c. of pituitrin and 15 minims of adrenalin were injected.

At 9-30 A.M. he was very restless, tossing about in bed and exclaiming that he was going to die. He passed a stool which was free from blood. His pulse was very feeble and couldn't be counted. The dressings on his foot were changed hourly owing to the copious oozing of blood. Respiration was hurried and short and the muscles of his face and hands were twitching. The foot of the bed was raised and an injection of $1\frac{1}{2}$ grs. of calcium lactate with 5 c.c. of sterile water was given intramuscularly.

At 10 A.M. he continued to spit blood. He was drowsy, apparently unconscious fitfully, his pulse was failing, and his extremities were cold. Hot water-bottles were applied and a sinapism over the heart. 2 c.c. of hæmostatic serum (Parke, Davis & Co.) with 5 c.c. of saline was given intramuscularly.

At 12-15 P.M. the dressings were again soaked through.

At 9-10 P.M. he was very restless and his pulse was imperceptible, but the bleeding from the gums had ceased. $1\frac{1}{2}$ grs. of calcium lactate in 5 c.c. distilled water was given intramuscularly.

At 8-45 A.M. on 20th August, 1923, the patient's condition was very bad. He had had a sleepless night, his pulse was very feeble, respiration shallow, and he was unconscious. $1\frac{1}{2}$ grs. calcium lactate was given intramuscularly.

At 10 A.M. deep sutures and tincture benzoin co. were applied to his foot,—after which the local bleeding temporarily subsided.

At 12 noon bleeding was as bad as ever; the dressings were soaked and had been changed twice since 10 A.M. The blood was now yellowish in colour and his extremities were cold. Hot water-bottles were applied.

At 6 P.M. his condition was desperate; unconscious; pulse imperceptible; and respiration very hurried. $1\frac{1}{2}$ grs. of calcium lactate was injected.

At 8 A.M. on 21st August, 1923, the patient's condition was the same as the night before, i.e., tossing in bed, face and hands twitching, retching and grinding his teeth. $1\frac{1}{2}$ grs. of calcium lactate with $\frac{1}{4}$ gr. of morphia was injected.

At 4 P.M. he was still unconscious; pulse was imperceptible; breathing stertorous; and bleeding continued. Adrenalin with pituitrin and strychnine was injected.

At 4-30 P.M. the dressings were again changed. $1\frac{1}{2}$ grs. of calcium lactate were injected and 1 pint of normal saline was given per rectum.

At 6-30 P.M. there was no improvement. $\frac{1}{4}$ gr. of morphia was injected.

At 7 P.M. there was still no change. Pituitrin and adrenalin were injected and the patient died at 7-45 P.M.

Autopsy.—The autopsy disclosed nothing of special interest beyond the escape of about 4 ounces of thin blood from the subarachnoid space when opened—which did not clot subsequently—and a general pallor of all the organs.

Remarks.—There is little reason to doubt that the snake responsible for this fatality was the saw-scaled viper "*Echis carinatus*" or the "kopper" of Sindis. The symptoms were typically those of a viperine toxæmia. Russell's viper—the only other viper occurring in Sind—is not likely to be found in Karachi, though it occurs sparingly outside the town. *Echis* is a common snake all over Sind, and occurs frequently within the precincts of Karachi.

I saw the case on the evening of the 18th of August. Blood collected so rapidly in the patient's mouth that he had to use his spitting mug two or three times a minute. I advocated calcium subcutaneously, and $10\frac{1}{2}$ grs. of the lactate were injected in 72 hours without controlling or abating the profuse hæmorrhage.

Three questions arise out of this case:—

- (1) Once the blood has been decalcified by an agent like snake venom is it possible to restore its calcium content by introducing calcium into the system or direct into the blood stream?
- (2) If No. 1 is possible, what dose of calcium is necessary to achieve this purpose?
- (3) If No. 1 is possible, within what limits of time is it possible to restore the calcium content?

With regard to question (2), one has to be on one's guard in injecting calcium into the blood stream, as in some cases extensive thrombosis has resulted. As far as I know this has only occurred in cases where the blood has been normal. It is probable that a dose which might occasion thrombosis in a normal condition of blood would have little or no danger in the abnormal state of the blood in a case of ophitoxæmia. All these questions could be solved by laboratory experiments. We ought to know whether calcium is of any use in snake poisoning, and if so, its best channel of introduction and the largest dose that can be administered with safety.

A FATAL CASE OF SNAKE-BITE (? *ECHIS CARINATUS*) DURING PREGNANCY.

By S. A. S. CHUHAR SINGH, I.M.D.,
In-Charge Civil Dispensary, Hurnai, Baluchistan.

ON 20th July, 1925, at about 8-30 P.M. a Mohamedan woman, aged about 30 years, was bitten just above the left malleolus by a snake which she described as a 'Landai' (the local name for *Echis carinatus*).

Tobacco leaves were applied, locally, and something was tied round the leg, but was

taken off very soon owing to the discomfort she complained of. She was brought to the hospital (Hurnai) on a donkey at 7-30 A.M. on 21st July 1925.

Briefly, the signs and symptoms were:—

1. Local swelling.
2. Local and general (head, abdomen and back) pain.
3. Bleeding (local, subconjunctival, from the mouth, genital and urinary passages).
4. Increasing weakness.
5. Drowsiness.

On admission she stated that she was five months pregnant. On the morning of 23rd July, 1925, pains started and at midnight a dead female foetus was born. The mother died at 4 P.M. on 24th July, 1925.

A CASE OF COBRA BITE SUCCESSFULLY TREATED WITH FITZ-SIMSON'S POLYVALENT ANTI-VENOMOUS SERUM.

By A. C. BHARADWAJA, L.M.P., P.S.M.S.,

House Surgeon, King Edward VII Hospital, Benares.

SARUPIA, a female patient, aged 25 years, was bitten by a cobra in the web between the left index finger and thumb at 12 A.M. on 5th August 1925. There were two punctured marks at the bitten spot. She was brought to hospital at 6 P.M. on the same day; during

The patient and the cobra with its fangs taken out.

the interval she was being administered nostrums by a *Madari* who had caught the cobra (shown in the photograph). They had

applied two ligatures one above the wrist and the other below the elbow joint. She was brought to hospital in a state of collapse and complete unconsciousness. The pulse at the wrists was quite imperceptible, temperature 95.5°F., perspiration pouring out, corneal reflex absent, extremities cold and clammy, the face cyanosed and breathing was hurried and stertorous.

There was paralysis of muscles of the tongue and face, resulting in the drooping of the eyelids and the lips. Saliva was dribbling down the chin. The left arm and forearm were very much swollen and blisters were forming all over them. The patient was at once given an injection of strychnine, the wound cleaned with Condy's lotion and 6 grains potassium permanganate was rubbed into the wound after it had been freely incised by an X-shaped incision. Then an intravenous injection of 10 c.c. of Fitz-Simson's polyvalent anti-venomous serum was given and the patient put to bed with hot water bottles applied to her feet. The ligatures were soon after removed.

At 9 P.M. the condition of the patient was considerably improved; the pulse had returned, the limbs were warm and the breathing was a little easier. Though the patient was conscious and could open her eyes she was unable to see anything. She could utter some words but the paralysis of the pharyngeal muscles (which could not be detected at the time of admission) was still complete and the patient was unable to swallow water.

Another intravenous injection of 10 c.c. of the serum and a subcutaneous injection of strychnine was given at this stage and two hours later the patient was chatting and sitting up in bed as if she had never been ill. At 11 P.M. she also passed urine in large quantity which she had not done since 12 A.M.

The patient was discharged completely cured on 7th August 1925.

The case is remarkable for its complete and quick recovery.

The polyvalent serum was injected as late as six hours after the poison had totally permeated the system, still it acted like magic.

Although in this case the snake had been caught and was known to be a cobra, it is claimed by the manufacturers that the serum being polyvalent is equally effective against any variety of snake venom. In view of the fact that over twenty thousand people die of snake bite in India every year, this treatment should prove very useful if it gives such good results as in this case.

I am very grateful to Lt.-Colonel J. S. O'Neill, M.C., M.D., F.R.C.S. (Edin.), I.M.S., the Civil Surgeon for kindly allowing me to publish these notes.

A CASE OF LARGE OVARIAN CYST NOT OBSTRUCTING DELIVERY OF A CHILD.

By B. SANJIVA RAO, L.M. & S.

DR. B. SANJIVA RAO, L.M. & S., writing from Masulipatam, Kistna District, reports a case of large ovarian cyst which appears to have developed during the course of pregnancy and which did not interfere with labour. A bucket and a half of fluid was drawn off at the operation which took place about a month after delivery of a healthy child.

Recovery from the operation was uneventful.

(Abstract from original communication).

INTERESTING EFFECT OF AN INSECT BITE.

By P. S. MILLS, M.B.,

MAJOR, I.M.S.,

Civil Surgeon, Gaya.

A MOHAMEDAN boy, aged about 11 years, was admitted into the Pilgrim Hospital, Gaya on 5th April, 1925, complaining of pain on micturition, and priapism.

The history was that about five days previously he had been bitten on the left foot by an insect that is called in the vernacular a *chharbinda*, and which is, as far as I can ascertain, a variety of dung-beetle.

Immediately after the bite he felt burning pain throughout the limb, and shortly after there was erection of the penis. The pain in the limb subsided in a few hours, but the painful erection persisted, and he sought relief for this condition.

On admission the boy was considerably distressed, and the penis was erect and so hard as to feel like cartilage. It was arched somewhat forwards and very tender. There was pain and difficulty on micturition, but no retention of urine.

He was treated with laxatives and opiates and the condition persisted for about five days after admission into hospital, and he was discharged well on the seventh day. There was no pyrexia, and nothing abnormal in the urine.

A CASE OF ARSENICAL INTOLERANCE?

By Y. S. ROW, L.M.B.,

Alipuram Jail Hospital, Bellary.

A MALE patient, aged about 35 years, came under my observation on 20th June, 1923, suffering from ulceration of the right cornea at its lower part following on an acute attack of interstitial keratitis. As he gave a positive history of syphilis some years back and as the same disease is one of the causes of the above condition, I decided to give the patient a course of neosalvarsan intravenously. The first injection of 0.3 grm. was given intravenously on 23rd June, 1923. He did not show any reaction

on that day. On the second day after the injection the patient developed an urticarial rash all over his body, more on its front aspect. There was no itching anywhere. On the third day of the injection, his evening temperature rose to 104°F. and kept up at that high level for four subsequent days without any remission whatever either in the mornings or in the evenings. He had none of the gastro-intestinal symptoms such as vomiting or diarrhoea. Except for the high temperature and rash, the patient did not complain of anything, nor was he much visibly affected by the above two symptoms. His lungs were carefully examined, no signs of pneumonia nor of any disease could be made out. The pulse and respiration ratio was normal. No cough at all.

On 30th June, 1923, the patient's temperature came down to normal by crisis and his rash disappeared on the following day. Since then he has made an uneventful recovery.

I did not continue the injection afterwards for fear of repetition of the above symptoms.

Remarks.—I can understand the cause of the urticarial rash which sometimes occurs in persons who have got an idiosyncrasy to arsenic, but what I cannot understand is the cause of the fever. Since the fever appeared on the third day after the injection I thought that it might be a mild septicæmia due to the infection through the needle of the syringe, though I myself very carefully sterilised the syringe as well as the distilled water. Or was the temperature due to any impurity in the preparation of '914' used by me? I have come across many cases of accidents with the same drug, of which there were many spurious imitations on the market in those days.

I do not think that the fever was due to the arsenic in '914' as then the temperature would have gone up the same evening after the injection instead of on the third day.

A CASE OF ARSENICAL INTOLERANCE.

By V. N. DEUSKAR, L.C.P. & S., L.M.D.

Haddo, Port Blair.

As there appears to be no doubt that *sulfarsenal* is the least toxic of all the arsenical preparations available to-day, and because cases of the toxicity of this drug have not so far appeared in the *Indian Medical Gazette* the following case, I think, would appear to be of special interest.

S. K. P., a clerk, aged 22, came under my treatment at Ahmedabad on 5th December, 1924, with all the signs of a fully developed secondary syphilis including marked cachexia which had totally disabled him to either stand up or walk about. The temperature chart which the patient had so carefully maintained from May to December 1924, was remarkably interesting. The "long continued fever" of nearly seven months' duration without one single day of apyrexia made up the most typical hectic chart of the text-books. Being too long it is unsuitable to be appended

here. Up to the date of my seeing him, the patient had not received any arsenical treatment, and even apart from the other signs and symptoms, the temperature chart alone was enough proof of the progress of an untreated case of syphilis. He was treated as follows:—

6th December, 1924.—Weight 91 lbs. 0.3 gramme of N. A. B. was given intravenously. The Jarish-Herxheimer reaction was nil. There was no "flare-up"; on the contrary this was the first day his evening temperature was normal although subsequently the patient was running a temperature as usual up to 23rd December, 1924. The dose was tolerated perfectly well.

13th December, 1924.—Weight 94½ lbs. 0.45 gm. of "914" was given intravenously. Immediately the patient burst out into a sharp, sudden paroxysm of short, suppressed coughing; at the same time there was itching all over the body and within less than three minutes the patient developed a profuse urticarial rash. The rash was well raised above the surface of the skin, intensely hyperæmic and of scarlet hue, the hyperæmia fading on pressure but reappearing instantaneously. 5 c.c. of intramine was at once injected intramuscularly and 1 c.c. of 1 in 1000 solution of adrenalin. The rash disappeared within half an hour but the cough was distressing and continued for five days more. There was also a general "flare up" after the injection; and the patient lost 5 lbs. in weight during the following week.

The treatment was suspended and the patient was put on to 8 grs. pot. iodide t.d.s. from 16th December, 1924. The fact that pyrexia of syphilitic origin is often only amenable to iodides was very striking in this particular case as from 23rd December, 1924, i.e., with a week's iodide, the disease was rendered permanently apyrexial.

When the weight of the patient was again 91 lbs., on 3rd January, 1925, subcutaneous injections of sulfarsenol were substituted as follows:—

4-1-25.—6 cgms.

6-1-25.—12 cgms.

8-1-25.—18 cgms.

10-1-25.—24 cgms.

There was no immediate reaction of any sort. The drug was tolerated as well as any other ordinary hypodermic injection. On the afternoon of 11th January, 1925, however, the patient complained of intestinal colic and began to vomit; not even a tablespoonful of iced water could be retained. Vomiting was persistent, lasted for 24 hours and required an injection of morphia.

There were no other signs of intolerance except this; the temperature was normal, the weight was not lost and there was no giddiness, headache or diarrhoea. The drug was withheld.

By 16th January, 1925, the weight of the patient increased to 94½ lbs. and treatment resumed as under:—

17-1-25.—30 cgms.

20-1-25.—36 cgms.

There was no immediate reaction either local or general but on 21st January, 1925, the same symptoms as on 11th January, 1925, recurred, and hiccup was an additional feature this time. Colic was now less complained of but the vomiting was much worse—the patient vomiting every 10 or 15 minutes. This, together with the hiccup, lasted 48 hours and required two injections of morphia; there was also much borborygmi. The drug was consequently again withheld. During the latter part of January the patient had gained good strength, was easily able to walk two miles and looked quite fit. Treatment was continued thus:—

5-2-25.—42 cgms. There was no local eruption or any general reaction.

11-2-25.—48 cgms.

Here the patient immediately developed exactly the same pulmonary and skin symptoms of arsenical intolerance as after 0.45 gm. of "914." In this case too the rash appeared within less than 3 minutes of giving the injection. This is an interesting feature inasmuch as it explains *how quickly sulfarsenol gets absorbed and reaches the general circulation after a subcutaneous injection.*

At this time neither intramine nor adrenalin was given but the patient was carefully watched. Both the rash and the cough disappeared after half an hour and the patient was up and about as usual and attended his duties.

It may be added that the bowels of the patient were opened before each injection and the urine was carefully examined and found normal each time. As would appear from the above the course of sulfarsenol was very cautiously proceeded with but the patient's intolerance for arsenic was very great and the nature of some of the symptoms he developed, far from usual.

A CASE OF OVARIOTOMY.

By RAI SAHIB CHHAGAN NATH,

Chief Medical Officer, Dungarpur State, Rajputana.

A HINDU woman, aged 42, a multipara, came to Bijaya Hospital, Dungarpur and stated that she was suffering from a growth in her abdomen for 23 years. She added that at first this growth had appeared on the left side and since then has continued to fill the abdominal cavity gradually. She has been a woman of thin constitution but has been in fairly good health.

Operation.—An incision in the median line 4 in. long below the umbilicus was made dividing the skin and fat. The sheath of the rectus muscles was opened and the recti were separated. After that an incision was made in the peritoneum and as soon as the peritoneal cavity was entered, the tumour was surveyed by hand all over its surface. A few adhesions were discovered but they being soft, readily broke down under the hand. The next step taken was to tap the cyst by plunging in a Spencer-Wells trocar and cannula. Tapping brought out with

some difficulty $7\frac{1}{2}$ lbs. of dark-brown fluid, without reducing markedly the size of the cyst. This naturally made me think that it should contain some solid matter. Accordingly the opening in the cyst was enlarged and the hand passed inside it, when greasy sebaceous matter was felt. This was scooped out by means of my hand and was found to weigh 15 lbs. of sebaceous material besides 12 ozs. of hair. When the cyst got thus emptied it was drawn forward and was discovered to be adherent to the omentum. The latter was ligated and divided. The pedicle was then securely tied off and also divided. The abdominal wound was closed in the usual way. The interior of the cyst was found to have been lined with hairs while the layers of its walls had embedded betwixt them growths of tiny bones here and there. The total weight of the cyst is tabulated as under:—

(1) Fluid matter	..	$7\frac{1}{2}$ lbs.
(2) Sebaceous material	..	15 lbs.
(3) Hairs	..	12 ozs.
(4) Sac	..	1 lb.

Total weight	24 lbs. 4 ozs.
--------------	----------------

The wound healed by first intention and the patient making an uneventful recovery left the hospital four weeks after the operation.

Photo. I.

Before operation.

The two photographs of the patient both before and after the operation vividly show her condition. In the after operation picture the tumour is shown hanging beside the patient.

After operation.

A CASE OF GENERALISED BLASTOMYCOSIS.

By GANAPATI PANJĀ, M.B.,

Assistant Professor of Bacteriology, Calcutta School of Tropical Medicine and Hygiene.

DIHANARATIA, a low-class Hindu female, aged about 8 years, inhabitant of Azamgarh, U. P., came with ringed lesions on the face, upper arms, legs and back.

The duration of the disease is five months and, as the patient's mother says, it started on the face, arm and leg simultaneously. There is no family history and no one in the patient's village is said to suffer from such a disease.

The disease was characterised by more or less circular patches, raised above the skin surface, healing in the centre and leaving scars; the margins showing papules, and nodules and pustules covered with scabs. Subjective symptoms were absent. There were no signs of congenital syphilis.

The disease was evidently a granuloma, but it might have been either syphilis, yaws, tuberculosis, tinea or blastomycosis.

Pathological Examination.—Scrapings were made from the margins and scales examined. A few spores of fungi were found. Examination was made for spirochætes by Dr. B. M. Das Gupta and none were seen.

The Wassermann reaction, which was kindly carried out for me by the assistant to the Imperial Serologist, was strongly positive.

A bead of pus from a pustule was examined by me with liquor potassæ and typical yeast-like organisms of blastomycetic dermatitis were found.

Spores of Blastomyces.

Treatment.—Mist. pot. iodide containing grs. $2\frac{1}{2}$ of iodide and locally ung. hydrag. am. dil. were given and the patient has shown a considerable improvement in two weeks' time. One week more will probably be needed for complete recovery.

Cases of blastomycetic dermatitis—localised and generalised—are often seen at the skin department of the Calcutta School of Tropical Medicine.

The diagnostic points are as follows:—

(1) Patchy lesion, pinkish, showing healing and scars in the centre and margins with

interrupted warty projections and pustules.

(2) Presence of typical fungi in the pustules when examination is made with liquor potassæ.

(3) Disappearance of the lesions with pot. iodide, X-ray and ung. hydrag. am. dil. or Lassar's paste.

A CASE OF MELANODERMA.

By GANAPATI PANJA, M.B.,
Asst. Professor of Bacteriology, Calcutta School of
Tropical Medicine and Hygiene.

K.D.P., Hindu male, aged 19, fair-complexioned, belonging to the Subarnabanik caste, of good health, came to me with blackish patches almost all over his body.

The patches were small, (vide photo 1) roundish, more black than brown, slightly

Photo I.

rough and most marked on the trunk. There was no irritation,

The patient was ill for 5 years and the disease started on the front of his neck spontaneously. The mucous membranes and the tongue are free from pigmentation. There is no family history and the Wassermann reaction was negative.

As the patches were rough and slightly raised above the skin surface, a microscopical examination was made of the scrapings from them and a very large number of yeast-like organisms, the so-called spores of Malassez,

were found, as shown in photo 2. A control was also made by examining scrapings from the unaffected skin in between the patches and a few organisms were found.

Photo. II.

Photo 2.
Spores of Malassezia.

It is possible that the condition of hyper-pigmentation or melanoderma is due to the above spores producing a slow and mild irritation of the melanoblasts. It is also possible that there is some disorder of internal secretions as well, as the patches were discrete and rarely diffuse. Bottle bacilli or spores of Malassezia usually give rise to diffuse pigmentation.

Treatment.—Sulphur soap to wash with, bismuth and hydrag. perchlor. lotion to apply in the day time, and salicylic and resorcin ointment to apply at night. I am touching a few spots with diluted trichloroacetic acid to produce desquamation and rapid cure. The patient is doing well.

A FATAL CASE OF SNAKE-BITE (? ECHIS CARINATUS).

Reported by Jemadar CHUHAR SINGH, I.D.S.M.,
I.M.D.,
Sub-Assistant Surgeon, Civil Dispensary, Hurnai.

About 5-30 A.M. on June 30th, 1925, a Mahomedan woman, aged about 30, was bitten on the left ankle by a snake which was described by her as a "landai" (the local name for the

Echis carinatus). Her husband brought her to the Hurnai Civil Dispensary at about 7-30 A.M. (He had tied his turban round her leg, but had taken it off again as she said she couldn't walk with it in place). On examination there were two punctures at the level of the left external malleolus, one of them very faint. They were incised, potassium permanganate rubbed in, and a bandage applied. The patient complained of pain in the left leg, side and shoulder, and head, and the foot was swollen.

At 8-30 A.M. 10 c.c. of calcium chloride grs. iv. in distilled water was injected into the neighbourhood of the bite. Half an hour later she said she felt stronger and that the pain was less.

9 A.M. Haemorrhage from the mouth.

11 A.M. Severe haemorrhage from the mouth; gums bleeding; marked oedema to the knee.

11-30 A.M. Calcium chloride injected.

4 P.M. Pain and haemorrhage continued. Condition fair.

8 P.M. Very severe pain in the foot and slight pain in head and shoulder. Pulse good.

At 2 A.M. on 1st July, 1925, the patient was still bleeding from the mouth and copiously from the bite; the whole leg being soaked. The wound was cleaned and dressed. As an injection of calcium chloride was refused, grs. xxx was given by the mouth and repeated twice later in the day. Her general condition was still fair.

12 Noon. Restless; severe pain in leg, back and head. Pulse and breathing slow. Bleeding continued. Banerji's inhalation tried.

12-30 P.M. She said she felt much better. Inhalation given repeatedly.

4 P.M. Still bleeding, but general condition fair.

8 P.M. She took some milk and rice. Complained of pain. Inhalation repeated.

At 6 A.M. on 2nd July, 1925, the patient had severe pains in the back, abdomen and head. Bleeding from the mouth had stopped but that from the wound still continued. She had vomited several times during the night.

12 Noon. No Change.

4 P.M. Drowsy; had severe pains in the head and back; leg very swollen, tender and hot; temperature 100° F., pulse 60. No relief after inhalation.

5 P.M. 1 pint of hypertonic saline given intravenously, after which she felt better. Pulse 80 and fairly strong.

9-30 P.M. Pain again very severe; had vomited twice. Drowsy; answers very slowly. Pulse 60; breathing slow; condition bad. $\frac{1}{2}$ oz. of brandy every four hours ordered. Failed to get needle into vein for hypertonic saline injection. Spirit. Ammon. Aromat., 1 drachm every two hours, ordered.

On 3rd July, 1925, the patient's condition was the same. Bleeding from the wound was less, but her husband stated that she had been bleeding from the vagina since the previous day.

9-30 A.M. Severe pain; sleepy; condition bad.

10 A.M. Succeeded in getting needle into vein and gave 15 ozs. of hypertonic saline before needle slipped out. No improvement; sinking slowly.

11-30 A.M. Adrenalin given hypodermically.

2-30 P.M. As before. Flatus giving trouble; unable to urinate but passage of catheter not allowed.

3-30 P.M. Feet and hands cold; pulse imperceptible; breathing very slow; drowsy; no paralysis.

4 P.M. Unconscious.

5 P.M. Died.

NOTES.

1. The œdema of the leg was greater than I have ever seen previously in a case of snake-bite.

2. Her husband stated that she was in the habit of catching snakes and that she had been bitten twice previously by "black snakes" without ill effects.

A CASE OF VOLVULUS OF THE ILEUM.

By M. E. TIRU CHELVAM, L.M.S.,

Assistant Surgeon, District Hospital, Ipoh, F. M. S.

A MALE Sikh, aged 30, was admitted into the District Hospital, Ipoh on 10th April, 1925, at 8 A.M. with a history of eight hours' illness. He complained of colicky pain about the umbilical region. There was no history of fever or vomiting. Temperature on admission was normal and pulse 82 and of good volume. He had not passed any motion for twenty-four hours. Examination of hernial orifices revealed a right reducible inguinal hernia. A simple enema was given and returned without any appreciable result.

In the afternoon the pain was generalised and the abdomen slightly tender. There was as yet neither vomiting, rigidity nor tympanitis. The pulse was good and the temperature 99.8°F. Two high olive oil enemas were given with poor result.

The patient was watched, and early next morning the abdomen was decidedly tender with moderate tympanitic distention, although there was no visible peristalsis. No flatus was passed. Temperature was 99.4°F. but the pulse had risen to 102 though still of good volume. He vomited a small quantity of bilious matter. A differential leucocytic count showed 89 per cent polymorphonuclears.

A provisional diagnosis of "obstruction with commencing peritonitis" was made and laparotomy decided on. At 9-30 A.M. when the patient arrived on the table his general condition was good, with a temperature of 99.2°F. and a good volume pulse of 132 per minute.

Under C. E., the abdomen was opened by the paramedian right rectus incision. A

quantity of brownish chocolate-coloured fluid escaped, and a volvulus of the ileum was found. The volvulus consisted of nearly two clockwise turns. The mesenteric pedicle showed attached to it, a long filamentous peritoneal band stretching from the right iliac fossa. This band had pulled the mesentery taut and formed an axis of rotation for the gut. The gut involved was the lower portion of the ileum of which forty inches was gangrenous. The distal end of the volvulus was within three inches of the ileo-cæcal valve. There were signs of commencing peritonitis, with patches of flaky deposit of lymph and discoloration of the parietal peritoneum.

As the patient was taking the anæsthetic well and the pulse showed little change, a primary resection of forty-two inches of the ileum was done. The cæcal end of the ileum was closed and the proximal end was anastomosed to the side of the cæcum. A rather medially placed anterior tænia of the cæcum provided a convenient site for the anastomosis.

The fluid was mopped out and the abdomen was sutured in three layers. The patient left the table with a pulse of 134 p.m. and while in bed was given two pints of 5 per cent. glucose in normal saline intravenously.

Early after-treatment consisted of the Fowler position, six ounces of 5 per cent. glucose in normal saline rectally every six hours and sips of glucose solution by the mouth. On the second, third and fifth days of the operation intravenous injections of 10 c.c. of half per cent solution of 'mercurochrome 220 soluble' were given, with reactions ranging from two to four degrees of temperature. An offensive liquid motion was passed the day after operation. This was followed by further motions when diarrhoea set in—as many as thirteen motions being passed on the fourth day of the operation.

The wound which looked perfectly clean and dry till the eighth day showed partial failure of union when the stitches were removed. A pelvic pocket of pus and a minute faecal fistula (occasionally discharging liquid stools) developed. The pus drained off gradually, and the fistula closed up completely on the sixteenth day of its appearance.

The subsequent course of the case was uneventful, the patient making a steady and complete recovery. The operation had incidentally caused the disappearance of his inguinal hernia.

The clinical features of the case were:—

(1) Absence of early or severe vomiting though obstruction was in the small gut.

(2) The very moderate distension of the abdomen no doubt caused by the high obstruction.

(3) Absence of visible peristalsis usual in other forms of obstruction. This point was

quite in keeping with the condition found, as visible peristalsis would be exceptional where a distended loop of gut pressed on the gut above.

I am obliged to Dr. R. Dowden, Principal Medical Officer, Federated Malay States, for permission to publish this case.

AN INTERESTING CASE OF NÆVUS.

By D. M. BHATAVADEKAR, M.B., B.S., B.M.S.,
CAPTAIN, I.M.S. (HON.),
Resident Medical Officer, Special Prison Hospital,
Thana.

THE patient, T. B. B., was first seen on 30th November, 1924, and was kept under observation until 4th May, 1925, when he was shown to the Grant College Medical Society as an interesting case of nævus.

The interesting features of the case were as follows:—

(1) One huge extensive flat patch of pigmentation continuous on front and back of trunk and extending beyond the middle line of his body. In its widest part it was 25 in. horizontally and 10 in. vertically with hair growing from the border in the front (specially marked). A few hairs were also scattered here and there over the patch on the back and some of them had turned grey. (It was noticed that the hair on his head had not turned grey; he was a man of 25 years of age.) See figs. 1 and 2.

The condition was stated to be present from birth and was apparently a progressive one as it

Gray hair.

Fig. 2.—Back view.

was reported to have progressed from behind forwards over the left shoulder in this order,—first the patch of pigmentation spreading forwards followed by a hairy border.

(2) An irregular rugged tumour with slightly nodular feel extending from between the scapulae across the back of the neck up to the junction of the occipital with parietals and temporals. In its widest part it was 12 in., in its narrowest part 9 in., and had a few softened and degenerated lumps in it which appeared like sebaceous cysts or lipomata. As compared with (1) the growth was raised but less pigmented, and the hair had grown sparsely. (See fig. 2.) The tumour was painless and could be lifted from the tissues underneath and moved from side to side for a short distance; its size was not diminished by pressure nor the colour altered, neither did it show any changes on temporary stoppage of breath as coughing.

(3) Patches of hairy mole varying from 1 in. to 4 in. in size scattered all over his body,—20 in number. (See fig. 2.) Two patches can be seen just below the waist band.

(4) Numerous small moles, about 200 in number, scattered over his body; the majority with hair and a few without hair. (See figs. 1 and 2.)

(5) A few small patches of pigmentation on palms and mucous membrane of the hard palate, i.e., on areas normally devoid of pigment. The left scrotum and left inguinal canal were empty. The testis on this side was said to have disappeared

Advancing
hairy border.

Fig. 1.—Front view.

after some illness; perhaps it atrophied after mumps, but there was no lump felt in the scrotum which gave the sensation of being occupied by fibrous tissue. Congenital phimosis was also present in this case.

COMMENT ON THE NATURE OF THE CASE.

Bland Sutton in his book on tumours says that hairy moles are recognised as much by their pigment as by their hair, i.e., the two are constant. Pusey in his book on dermatology says moles are pigmented nævi, i.e., pigment and blood vessels are in excess and constant. Combining the two definitions, the hairy mole would seem to consist of three elements—all in excess of the normal—i.e., hair, blood vessels and pigment, which may, therefore, be termed *nævus pigmentosus et pilosus*. The case under review well shows this condition and also exemplifies other varieties of nævus such as flat (n. spilus), raised (n. verrucosus), and fatty (n. lipomatosus) nævi described by Pusey in his book on dermatology; the unique feature of the case being the presence of all these varieties in one person.

Regarding size, shape, distribution and number the case is also unique as nævi rarely exceed the size of the hand and though the shape varies with size, so that with larger nævi we find greater elevation, more hyperkeratosis, more papillomatous or warty surface, and a more exaggerated growth of hair, in this case we found the flat variety was more marked than the raised and hair growth was not abundant except at the growing margin. The number is usually one or two but may be unlimited; frequently when no large nævus is present there are many moles. In this case both small and large varieties were present, the former in large numbers (about 200).

Distribution is generally irregular and asymmetrical and may be upon any part of the body, but sites of predilection are the face,—especially forehead, neck and back; or may be along cutaneous nerves, blood vessels, metameric segments of skin and embryonic sutures. In the present case moles were scattered all over the body and were not confined to any one particular region, blood vessel or nerve, thus differing from a neurofibroma. In (2) the condition was sharply limited at the junction of the occipital with the temporal, whereas if the temporal was involved the condition might have been mistaken for cirroid aneurysm. The condition was present from birth, therefore the excessive pigmentation must have been due to deposit of excess of melanin by prickle-cells. Its presence on the palms and the mucous membranes of the palate-sites normally devoid of pigment is curious.

The exact nature of these growths can only be told by microscopic examination of a section of the growth. This was not done lest a malignant change occurred—a real danger ever present in such cases—and because practically nothing can be done by way of treatment in such an

extensive condition which, however, was not painful and only slightly disfiguring.

We, therefore, conclude with Pusey that nævi are developmental defects and that the causes of their occurrence are altogether obscure with no hereditary tendency (although in this case it was stated that the great-grandfather had a very similar pigmentation of skin).

My thanks are due to my cousin, N. B. Bhata-vadekar, B.A., M.B., B.S., for pointing out the detailed literature in Pusey's book on dermatology, and to Colonel Murray, I.M.S., the Inspector-General of Prisons, Bombay Presidency, for his kind permission to publish this case.

ACCIDENTAL "MARKING-NUT" DERMATITIS.

By R. W. SCANLON,

Assistant Surgeon, Civil Hospital, Berbera,
British Somaliland.

THE "marking-nut" in India, according to Lyon's "Jurisprudence," is occasionally used with criminal intent and sometimes therapeutically.

The case responsible for this note commenced with the therapeutic application of the juice of the marking-nut for ringworm of the scalp.

The patient after the application of the juice to his scalp did not consider the likelihood of vesication of parts with which the juice came in contact, and noticed after 4 days an erythematous patch on his left arm over the biceps region which reminded him that he had been using his arm as a pillow shortly after he had applied the juice to his scalp.

Twenty-four hours later the patch had the appearance of herpes and was extremely irritable. He also noticed isolated herpetiform patches on his left forearm and wrist which he attributed to the secretion from the ruptured vesicles. Crops of vesicles and papules appeared on the chest also.

The chief complaint of the patient was intolerable itching. He denied any tingling or pain before the crops appeared.

It is difficult to state whether the secretion from vesicles produced by the juice also has the effect of a vesicant, and it was intended to try this on the patient and a volunteer but the former refused and has not been seen since.

The scattered crops of vesicles were in all probability the result of splashing with some of the juice when it was applied to the head, and the large patch on the arm the result of direct contact.

The history of the case and the presence of the large 'contact' patch were the main facts in the diagnosis which would have been otherwise very difficult.

My thanks are due to Dr. R. S. Taylor, Senior Medical Officer, Somaliland Protectorate for permission to record these notes.

Indian Medical Gazette.

OCTOBER.

LEPROSY RELIEF FUND.

It is likely that this fund will soon be closed. The subscriptions which have been received up-to-date are, on the whole, distinctly disappointing, they will not be sufficient for the institution of a plan of campaign which will enable India to make a great forward stride towards the solution of the leprosy problem. Leprosy has in the past been the Cinderella of tropical diseases and it is only the great efforts of Sir Leonard Rogers and Dr. Muir which have made India a factor of importance in the advancement of our knowledge of leprosy. It is now high time that the discoveries of these and other workers should be made available for the prevention and cure of leprosy in this country. It is believed that the policy of the governing body of the relief fund will be to promote research work in leprosy, to provide facilities for training medical men who will be engaged in the treatment of the disease, to improve the teaching of leprosy in the medical colleges and schools and to make grants to the clinics which will be opened for treatment of the disease. It is expected that a considerable proportion of the contributions from each province will return to the local committee in the form of grants from the central fund.

There is thus a special incentive to local committees to raise as much money as possible. It is obviously undesirable that the whole of the funds should be spent in the form of grants in aid of the local bodies, if this were done there would be no money for research, teaching and propaganda, all of which activities can be carried out more efficiently by a central organisation than by local effort.

Some of the provinces have not lived up to their reputation for generosity in the matter of contributions. Bengal has done very badly while Bombay has done fairly well.

It is anticipated that the total yearly income of the fund will hardly exceed a lac of rupees. At the present time something like twelve lacs of rupees are spent yearly in providing for a small fraction of the pauper lepers of India, so that it is obvious that a lac a year would be a drop in the bucket as far as provision of hospitals and colonies is concerned. For this reason it seems to be a wise policy on the part of the committee of the fund to concentrate their efforts on research, teaching, propaganda and the aiding of early treatment clinics. Even with the small sum that is available a good deal can be done in these directions, but unless a more generous response is made before the fund closes it is not likely that the Association will

be able to consider any ambitious schemes for dealing with the leprosy problem in India.

We do not expect our readers to contribute large sums but they might well bring the claims of the fund to the notice of their wealthier patients.

THE CAUSE OF CANCER.

DURING the early days of August the curiosity of the medical profession in India was much whetted by the advance press publicity which was given to the work of Dr. W. E. Gye and Mr. J. E. Barnard on the subject of the causation of cancer so that their communications to the *Lancet* of July 18th have been read with special interest. To us in India the one great outstanding feature of cancer is the fact that many of the forms of the disease seen in this country appear to be definitely associated with chronic irritation of various kinds, and in spite of many pieces of valuable experimental work which have been done by others the production of the disease in rabbits and mice by painting with tar appeared to have the closest bearing on the causation of the disease. It was by no means certain that irritation in itself was the cause of the disease but it was clear that the experimental animals and many of the human victims of cancer would not have suffered if they had not been subjected to prolonged local irritation. From the practical point of view irritation was thus shown to be an essential factor in many cases whatever other factors may have been at work. It is freely admitted that the change produced in the tissues by irritation may only be a cause in so far as it prepares the ground for some causal factor, but if so the causal factor must have a pretty wide distribution and must be lying in wait ready to assert itself when the necessary local conditions are brought about. Of the other significant pieces of experimental work it is necessary to refer to the work of Ribbert who showed that the disease in the beginning is purely local, to that of Hanau who showed that certain rat tumours could be transplanted from animal to animal, to that of Peyton Rous who transmitted a fowl sarcoma by the injection of filtered cell-free extracts of the tumour, and to the work of Fibiger who produced cancer in the stomach in rats by infecting the animals with a nematode. We now have the work of Gye and Barnard who have brought forward strong evidence that there is a filtrable virus which cannot by itself cause cancer, but which in conjunction with virus-free cancer extracts can produce malignant growths under certain conditions.

It is now asserted that the work of Gye and Barnard has been anticipated by Prof. Keysser for whom some leading German scientists claim the credit of the discovery. Of this it is likely that more will be heard in the near future, but it is impossible to deal with the question until the facts are available, and in the meantime we are concerned with the reports of Dr. Gye

and Mr. Barnard as published in the *Lancet*. Dr. Gye points out that filtrability of a virus is often relative property for instance some clearly visible spirochaetes are filter-passers, while the virus of vaccinia though a filter-passer under certain conditions is non-filtrable as it occurs in calf lymph. He next details the best method of obtaining an infective filtrate, he grinds up healthy tumour tissue with sterile sand and mixes it with Ringer's fluid then coarsely filters the material through layers of paper pulp and sand and passes the filtrate through a Chamberland 12 candle. The best culture medium for the virus is Hartley's broth to which is added 0.2 per cent. KCl. The broth is sterilised by steaming and fresh rabbit serum is added. Special precautions are needed to ensure that the tumour material is not contaminated by secondary infection during the process of excision. The injection of 1 c.c. of a tumour filtrate from Rous' chicken sarcoma caused tumour formation in the pectoral muscle of a chicken, but the filtrate ceased to be effective in a few days, not because the virus has died out but because of the disappearance of an accessory chemical factor, as was shown by adding primary culture of the virus to a virus-free tumour extract when the combination of the two substances caused a tumour, though each of them singly was ineffective even in large doses. It was thus shown that both the virus and a tumour extract was needed to cause the disease. It was found that the virus could be separated to a large extent from the tumour filtrate by centrifugation and hence is probably particulate while the other factor could not be so removed and so is probably a chemical substance. It was further found that the virus is effective in causing tumours in many kinds of animals and therefore is not specific for any particular animal, while the virus-free tumour extract is strictly specific; so that an extract from a tumour of a mouse when injected with the virus will not cause a tumour in a pigeon but will produce a tumour in another mouse. Apparently the virus which is to some extent capable of being cultivated is one of the common factors in tumour formation and it appears to be the same in tumours from various kinds of animals, while the essential adjuvant which results from some change in the affected tissues due to irritation or other cause, is strictly specific for each animal. It remains to find the nature of the chemical adjuvant and Dr. Gye says that some of the "relatively unimportant" chemical irritants like coal tar and paraffine are already known. These may be unimportant in that they are not responsible for the causation of a large number of cases of human cancer, but they are surely of vast importance as definite examples of the chemical factor in cancer causation and hence as clues to the discovery of the nature of this factor. It would also appear to be reasonable to argue that the virus which is at work is of widespread distribution while the suitable tissue condition which enables the virus to become effective is the more

important and the more easily controlled factor in cancer causation. The uniformity with which the Japanese workers Yamagiwa and Ishikawa produced cancer by application of tar and the frequency with which the *kangri* can cause skin epithelioma among Kashmiris suggest that the virus is almost universally distributed in nature and that the local conditions determine the frequency or rarity of the disease. We have not heard the last of the virus, its discovery may have very far-reaching consequences, but it is important that attention should continue to be paid to the tissue irritants which may turn out to be the more important factors in the long run. The contribution of Mr. J. E. Barnard is very remarkable. Mr. Barnard is a business man who has for long been known as a leading expert in microscopy and by specially designed methods of dark-ground illumination which are described in the paper he has been able to obtain satisfactory photographs of the filter-passing virus of pleuro-pneumonia of cattle and of the much smaller virus of the Rous fowl sarcoma.

The appliances used are exceedingly ingenious, they appear to be essentially the same in principle as the Zeiss quartz condenser by which objects can be photographed with very short wave lengths of ultra violet light, but apparently the quartz objectives which used to be listed by Zeiss have not been employed, these had the disadvantage that they could not be used for visual purposes and so it is likely that their greater resolving powers cannot readily be made use of in practice. Altogether it would appear that an important advance has been made in the cancer problem, one which may even lead to its final solution, but there are obviously two separate lines of attack on the cancer problem, the one which is suggested by the work of Dr. Gye which consists in trying to discover the nature and distribution of the "virus" while the other is the discovery of the local conditions which prepare the field for the action of the virus. The old question of the soil and the seed is raised; our attention is specially called to the seed by Dr. Gye's work, but if the seed should turn out to be so widely distributed in the bodies of animals as to be almost universal and if it is not possible to eradicate the seed by vaccines or other means, we shall be compelled to fall back on the other line of attack which will consist in finding out how the soil is prepared for the seed and in preventing that preparation from taking place. In many forms of cancer we do know how the soil is prepared, for example in *kangri* cancer, in tar cancer, in paraffine cancer, in radiologist's cancer and in several other forms of the disease. It is difficult to understand why these obvious clues have not attracted greater attention in the past, and it is to be hoped that they will not be neglected by the many skilled investigators who are devoting themselves to the discovery of the cause of cancer.

Even if the factor which has been discovered by Dr. Gye is proved to be the virus of cancer,

it is far from constituting a solution of the cancer problem. A solution will only have been obtained when we know how to prevent or to cure the disease, and it is to be feared that many victims of cancer in the next generation will have too good grounds for complaining that we have not enabled them to escape from the dread disease. We can already tell the Kashmiris how to avoid their *kangri* epithelioma, we can tell the radiologists how to avoid cancer of the hands, we can tell the *pan* chewer how to avoid cancer of the mouth, if we follow up these very obvious clues we may even be able to find out how to avoid most forms of cancer, merely by removal of some unfavourable environmental condition. Is it that such a line of attack is too obvious and too simple to be worthy of the attention of investigators? Anyhow the sky is clearing a little, perhaps we are nearer to the dawn than we imagine.

SPECIAL ARTICLES.

PATHOLOGICAL EVIDENCE BEARING ON DISEASE INCIDENCE IN CALCUTTA.

By SIR LEONARD ROGERS, C.I.E., M.D.,

F.R.C.P., F.R.C.S., F.R.S.,

LIEUTENANT-COLONEL, I.M.S. (Retd.).

(Glasgow Medical Journal, January, 1925.)

THIS paper is of such interest and importance that we have no hesitation in giving our readers the benefit of extensive extracts from it. Much has been written on the incidence of special diseases in the tropics, but far less is known regarding that of world-wide diseases in hot countries. Nor is this surprising in view of the very backward position of vital statistics in such countries as India, where only a very small percentage of fatal illnesses are seen and diagnosed by qualified medical men, while the only accurate data refer to the selected men of the middle period of life of the British and Indian armies, and of the causes of death of the temporary inhabitants of the jails. In a few of the largest cities of India the death returns are of some value, although far inferior to those of British towns, but the statistics of the mortality among the general civil population, returned as they are by uneducated village watchmen, are so grotesquely inaccurate that, during an inquiry in the fever-stricken Bengal district of Dinajpur in 1904, Sir Leonard found that 65 out of every 66 cases of such a definite disease as dysentery had been returned incorrectly as under the elastic heading of "fever," which commonly includes about 90 per cent. of all the deaths. For accurate information regarding disease incidence in India we must therefore turn to the post-mortem records of the few medical colleges, those of the premier one of India at Calcutta having exceptionally good records.

The results of 1,600 post-mortems are analysed in this paper and compared with 1,000 medical post-mortems analysed on precisely similar lines at St. Mary's Hospital, London. Sir Leonard has also classified 1,000 tumours of which microscopical examinations had been made in the St. Mary's pathological laboratory for comparison with 1,190 tumours examined by him in Calcutta between 1910 and 1919 inclusive.

Percentages of Total Calcutta Mortality Due to Tropical Diseases.

Disease.	1,600 post-mortems.		Vital statistics, excluding children under 5 years.
Malaria ..	1.56	9.99	6.2
Kala-azar ..	8.06		
Plague ..	0.37

Infantile liver		2.4
Ankylostomiasis ..	0.19		..
Beri-beri ..	0.37		0.1
Leprosy		0.4
Total ..	33.43		29.35
+ Half-doubtful fevers		3.9
Total		33.25

Fevers and dysenteries form the great majority of tropical diseases in the Calcutta series, the total amounting to just one-third of the whole in each series; percentages of the different non-tropical diseases can be obtained by a very simple calculation from those of the total number of cases.

In discussing the comparative prevalence of different diseases in the two series it will frequently be necessary to take into account the very great differences in the age distribution of the two sets of figures, especially as regards those under 10 and those over 50 years of age.

Age Incidence of Total Medical Post-mortem, in Calcutta and London.

Years.	Calcutta.		St. Mary's Hospital, London.		Census Figures.	
	All ages.	Over 10 years.	All ages.	Over 10 years.	Bengal.	England.
Up to 10	2.5	..	16.9	..	28.62	20.96
11 to 20	13.4	13.8	10.2	12.2	21.93	18.98
21 to 30	35.3	36.3	12.1	14.6	17.82	17.32
31 to 40	27.4	28.1	12.3	14.8	13.77	15.53
41 to 50	13.3	13.7	16.5	19.9	9.51	11.53
51 to 60	5.8	6.0	20.0	24.1	5.19	7.98
Over 60	1.9	2.0	12.0	14.4	3.16	8.02
Over 50	7.7	8.0	32.0	38.5	8.35	16.00
Over 40	21.0	21.7	48.5	58.4	17.86	27.53

Children up to 10 years are far fewer (2.5 per cent.) in the Calcutta than in the St. Mary's figures (16.9 per cent.), as is also the case between 51 and 60, namely, 5.8 per cent. in Calcutta to 20 per cent. in London, and above 60 with only 1.9 in Calcutta to 12 per cent. at St. Mary's.

The percentages of deaths in the two post-mortem series in the main groups, together with the Calcutta vital statistics for all ages over 5 years are given in a table from which tropical diseases are excluded.

Percentages of Deaths in the Main Groups of Diseases.

Group.	Calcutta post-mortems.	London post-mortems.	Calcutta vital statistics, less children under 5 years.
General
Tuberculosis ..	9.23	6.1	9.5
Circulatory ..	21.93	13.4	21.5
Respiratory ..	10.50	20.3	5.4
Digestive ..	27.13	16.8	48.7
Urinary ..	12.00	7.5	7.2
Nervous ..	6.35	8.6	1.8
Malignant Disease ..	7.41	11.9	4.1
Remainder ..	4.59	13.8	1.21
..	0.84	1.6	..

The Indian series show considerable excess in general, and especially in tubercular disease, and in diseases of the respiratory and digestive systems, while the English series show great excess in circulatory diseases and in malignant tumours, and less marked increase in those of the nervous and genito-urinary groups, in spite of tropical diseases having been excluded in estimating the Calcutta data. A further analysis of the principal diseases of the different groups is made.

Total	.. 13.4	21.93	14.76	21.4

Anæmia is more common in Calcutta. Leukæmia, on the other hand, was more frequent in London, but in Calcutta, the disease is more likely to be overlooked in view of the frequency of very large spleens due to kala-azar and chronic malaria.

Diabetes is shown as being several times more common as a cause of death in London than in Calcutta. This disease is not common among the very poor classes, who comprise the vast majority of the post-mortem cases, and cannot afford the quantities of sugar consumed by their wealthier compatriots, indicating that the prevalence of diabetes among the latter is of dietetic origin, and not due to any racial characteristic.

Diphtheria caused only 0.18 deaths in the Calcutta post-mortems as compared with 0.5 in the London series, but this is due to the rarity of admissions, and still more of post-mortems on children in the Calcutta Hospital, for the Health Officer's figure is 0.37 including children, which is probably below the truth on account of defective diagnosis.

Septicæmia, including pyæmia, but not puerperal cases, shows the high rate of 3 per cent. in the Calcutta post-mortems and 1.2 per cent. in the Health Officer's figures, omitting children under 5 years, against 0.5 per cent. in the London post-mortems, which well reflects the greater dangers of septic infections in the hot, moist, germ-laden atmosphere of Bengal, and is of great interest in connection with the universal secondary infection of the originally sterile pus of amebic liver abscesses after the open operation in Calcutta and other damp tropical climates, as was shown by Sir Leonard twenty years ago. Hence his advocacy of the now generally adopted method of aspiration, combined with the administration of ipecacuanha or emetine, which has reduced the death-rate from the former figure of 60 to 70 per cent. to only 1.6 per cent. in 186 recent cases treated by his methods by Dr. K. K. Chatterji in Calcutta.

Tetanus shows the very high figure of 2.05 per cent. in the medical post-mortems in Calcutta, against only 0.1 per cent., or one-twentieth as many in London, while the Calcutta Health Officer's returns show the appalling rate of 6.04 per cent. of the total deaths for all ages, although in those over the age of 5 years the rate is

only 1.1, which is still eleven times that of the London series. Of the total number of 906 deaths in the 1921 health returns, no less than 785 were infants, nearly all due to infection through the umbilical cord on account of the insanitary dressings, often including cowdung, applied by ignorant Indian midwives. The frequency of tetanus in adults is also well known, and is easily explained by the discovery by Sir Leonard, many years ago, that if a minute pinch of dust of a Calcutta main road was placed under the skin of rats, five out of six died of tetanus. This led him to advocate the general prophylactic use of anti-tetanic serum in all wounds and abrasions contaminated by dust at this hospital, and it is of interest to note that, although 20 cases occurred in the first 1,000 post-mortems he performed in Calcutta, among the last 600 the number was only 2, indicating the great preventative value of the serum.

Typhoid fever caused 1.21 per cent. of the deaths in the Calcutta as compared with 0.1 per cent. in the London post-mortems, the very low London rate being only partially explained by such cases being rarely admitted to the general hospitals at the present day, while the much higher Calcutta hospital figure is confirmed by the Health Officer's return of 2.9 per cent. in those over 5 years and 2.2 in the total cases. Yet, when Sir Leonard went to the Calcutta Medical College Hospital in 1900, it was very generally held by the medical profession in Calcutta that typhoid scarcely ever occurred in natives of India, while only three cases had been recognised in ten years in the large Medical College Hospital, although by the Widal test he was able to show, in 1900, that there were six unrecognised cases in the wards at one time, such cases being up to then returned as remittent malaria, and one of the first papers he published after going to Calcutta was entitled "Typhoid as a common continued fever of natives in Calcutta." He found later that typhoid is particularly common among Indian children, and it is now generally acknowledged that the incidence of typhoid is far higher in India than in this country, and that all Europeans going to reside in the tropics should be inoculated against typhoid.

Tuberculosis.—In a previous paper Sir Leonard recorded a detailed analysis of the tubercular cases among 3,341 Calcutta Medical College post-mortems, showing that in 18.3 per cent. of the medical cases tuberculosis was the cause of death, while in 7.2 per cent. more it complicated other fatal diseases, including a number of latent lesions of recovered tubercle, making a total of 25.5 per cent. revealing well-marked tubercular lesions. Yet, a very experienced I.M.S. officer at the 1892 Berlin International Tuberculosis Congress, speaking as Government of India delegate, stated that phthisis and other lung diseases were rare among natives of India, apparently on the strength of a statement he made that only 3 per cent. of the deaths which had been inquired into in one province had been returned as due to phthisis—a striking example of relying on the official returns of deaths reported by untrained and ill-paid agencies, and ignoring the available Calcutta post-mortem records, where this very officer worked during most of his service. The figures show that tuberculosis accounts for no less than 21.93 per cent. of the non-tropical Calcutta post-mortems, against 13.4 per cent. in the London data, by far the highest figure for any one disease, and much in excess of any of the common tropical diseases. In considering the incidence of the different classes of tubercular disease, the very small proportion of children under 10 years in the Calcutta series must be taken into account, for he finds that the combined figures of general tuberculosis and tubercular meningitis form 62.7 of the London, but only 6.7 per cent. of the Calcutta cases, were in children not over 10 years of age, so that the real incidence of these acute types must be considerably greater in the Calcutta series, instead of being somewhat less as indicated by the figures. On the other hand, the three-fold greater incidence of pulmonary cases in the Calcutta series is no doubt partly due to such cases being less commonly

admitted to London general hospitals, although the fact that the Calcutta Health Officer's returns show an incidence of 20.4 per cent. of pulmonary phthisis deaths among non-tropical diseases, or higher even than the post-mortem figure, while the city tuberculosis death-rate was 2.14 per mille of population fully confirm the terribly high tubercular incidence in Calcutta, due largely to overcrowding, assisted by the purdah system, as proved by the rate among females being three times as high as among males. Moreover, in an inquiry into the causes of death in the malarious Bengal district of Dinajpore in 1904, he obtained clear evidence of not less than 9 per cent. of the deaths being due to pulmonary tuberculosis in the villages, while it is also certain that the disease runs a more acute course in Bengal, as well as in Bombay, as shown recently by Dr. A. Powell, than in Great Britain; so the importance of the tuberculosis in India can scarcely be exaggerated.

Another point is the frequency of primary intestinal tuberculosis with extensive intestinal and abdominal glandular affection, but little or no involvement of the lungs. In several cases Sir Leonard inoculated rabbits with such tubercular material without ever producing the bovine type of the disease—an interesting fact, which is in accordance with the rarity of surgical forms of tuberculosis in Calcutta as compared with Europe which he attributed to the absence of infection of cattle to any material extent in Bengal and most parts of India, and the universal custom of boiling milk before it is consumed by Indians. The explanation of the frequency of primary human intestinal tuberculosis of the bowel in Calcutta which is infection through food owing to the Bengali habit of unrestrained expectoration by phthisical as well as healthy persons. Secondary intestinal infection in pulmonary tuberculosis was found in no less than 65.9 per cent. of his Calcutta series, against 23.9 per cent. in Osler's data, while laryngeal tubercle only occurred in 9.1 per cent. in Calcutta against 18 to 30 per cent. of Osler's and 50 per cent. of Percy Kidd's London figures—these differences being explainable by the greater stress of cold climates on the larynx and in hot ones on the digestive system. Tubercular pericarditis and pneumothorax were also rather more frequent in Calcutta.

Lobar pneumonia, so far from being rare in Bengal, actually equals tuberculosis of that organ as the greatest single cause of death in the Calcutta records with 16.03 per cent. against 16.10 for phthisis, and it is also a good second in the Health Officer's returns for all over 5 years with 17.9 against 20.4 per cent. for pulmonary tuberculosis, while it is essentially a disease of the prime of life, for no less than 70 per cent. occurred between the ages of 21 and 40, so that when a well-nourished body of such an age appeared on the post-mortem table the cause of death was generally lobar pneumonia or cholera. The race incidence was highest among the Hindus, distinctly lower among the Mahomedans, and much below the average in the few European subjects of the earlier records, which is in accordance with the relative resisting powers of the three classes to cholera and other acute infections. He found that 42 per cent. occurred in the four coldest months of November to February, 31 per cent. in the four very hot months of March to June, and 27 per cent. in the four rainy ones of July to October, with intermediate temperatures but a smaller diurnal variation than in the other two seasons, and commonly extending over 20°F., and sometimes to over 30°F. when the frequent sudden heavy rain storms occur in the hot season. A still more important cause of the remarkably high pneumonic rate is a combination of overcrowded, often one-roomed houses, of the poorer classes in Bengal, and the favourable influence of the hot climate on the life of the delicate streptococcal group of organisms outside the human body increasing the chances of infection. Gangrene of the lung is a much more common sequela of lobar pneumonia in Calcutta, apparently due to deficient resisting power of the Bengalis.

Others ..	1.1	1.59	1.30
Total ..	20.3	10.50	5.19

Broncho-pneumonia shows very similar incidence in the two post-mortem series, of 6.1 and 5.8 respectively for Calcutta and London, but the health returns for Calcutta show the much higher figure of 13.9 per cent. for all over 5 years of age, largely due to the great influenza epidemic in 1918-19. The comparatively low hospital rate is mainly due to the few admissions of children to the wards.

During the influenza outbreak, a conglomerate type of broncho-pneumonia, not previously seen, at once became extremely prevalent, the observation of which should enable a serious influenza outbreak to be immediately recognised.

Bronchitis shows precisely the same features as broncho-pneumonia, with which the former disease so frequently terminates in both the young and the old, so further comment is unnecessary. Pleurisy and empyema, as well as other rarer lung diseases, also show very similar figures in the two post-mortem series.

The total deaths from the above lung diseases are greatly in excess in Calcutta post-mortems, namely, 27.12 to 16.8 per cent., due entirely to the great amount of lobar pneumonia, while the much higher figure of 47.9 per cent. in the health returns for Calcutta is due to all secondary terminal lung affections tending to be certified as pneumonia or bronchitis, while in my tables, deaths from terminal lung complications of such diseases as kala-azar, dysentery, etc., have been entered under the primary disease.

Circulatory Diseases.

Here we meet with precisely the opposite condition to lung diseases, namely, twice as high an incidence in the London as in the Calcutta post-mortem series, the explanation of which is of very especial interest, mainly on account of the nearly, if not complete, absence of rheumatic endo- and pericarditis in Bengalis, who have not visited a cold climate or a hill station. It is seen that the London series gave 3.7 per cent. of deaths from rheumatic endocarditis, often complicated with pericardial inflammation, against 0.0 in the 1,600 Calcutta cases, but still stronger evidence is afforded by the fact that in the 4,800 post-mortems in the thirty-seven years up to 1909 there was only one case returned as rheumatic endocarditis, and that was in an Anglo-Indian subject, who had almost certainly visited a cold climate. In the pathological museum of the Medical College, dating from that of the Medical and Physical Society of Bengal, founded about 1825, there is only one specimen from a Bengali subject recorded as having been due to "rheumatic fever" and resembling that condition anatomically, although in the absence of

bacteriological examination it is impossible to exclude endocarditis due to either the pneumococcus or the gonococcus—the latter, in particular, not very rarely producing articular conditions in Calcutta not unlike the rheumatic variety.

Ulcerative or malignant endocarditis, on the other hand, is by no means rare, the twenty years' Calcutta records showing 1.5 per cent. against 2.6 in the London series, where rheumatic endocarditis may develop into the ulcerative form. Sir Leonard found the pneumococcus by far the most frequent organism in the damaged valves, as might be expected from the incidence of lobar pneumonia. It is also of interest to note that in the Calcutta cases the aortic valve was considerably more frequently affected with the ulcerative disease than the mitral, while the reverse is the case in Osler's figures, doubtless on account of the rarity of antecedent rheumatic endocarditis in Bengal. In the London series of rheumatic endocarditis the average age of the patients was 14.3 years, while that of malignant endocarditis was 32.6 years, while the Calcutta series of malignant endocarditis works out at just 32 years, or the same as the malignant endocarditis cases in London, and more than twice as high as that of the rheumatic endocarditis ones; which once more confirms the absence of any material amount of rheumatic endocarditis in Calcutta.

The percentage of cases in which the primary cause of death was attributed to pericarditis was 0.75 in Calcutta, but only 0.4 per cent. in London, just the reverse of the rheumatic endocarditis, indicating a difference in etiology. Only 1 of 102 cases of pericarditis or less than 1 per cent. was classed as possibly of the rheumatic form; 14 were of septic origin accompanying pyæmia, dysentery, liver abscess, etc.; 10 were tubercular; 1 complicated Bright's disease and 2 cirrhosis of the liver, and the remaining 74 were secondary to pneumonia in 65, empyema in 5, acute pleurisy 3, and congestion of the lung in 1. Of the 65 secondary to pneumonia, in 32 the pericarditis was marked, and in 33 it was slight, usually only at the base of the heart around the large vessels, not resembling the rheumatic form, and unaccompanied by endocarditis, except in one ulcerative case—a very different state of affairs to rheumatic endocarditis, which is so commonly complicated by pericarditis. One doubtful case is the only possible evidence of rheumatic endocarditis in 4,800 post-mortems spread over thirty-seven years. The frequency of pneumococcal pericarditis, on the other hand, was often confirmed by bacteriological examination, while it was secondary in an equal number of cases to pneumonia, taken with the great frequency of lobar pneumonia. In Calcutta, the pneumococcus takes the place of the rheumatic fever organism as the principal cause of pericarditis in Bengal.

Valvular cardiac disease.—In London mitral valvular disease was the primary cause of death in 4.3 per cent., and aortic valvular affections in only 2.6 per cent., whereas in Calcutta the figures were reversed, with only 0.93 per cent. of mitral disease, or but little over one-fifth of that in London, while aortic disease was responsible for 2.7 per cent., or nearly three times as many as mitral. This suggests that the comparative rarity of mitral disease, and especially of mitral stenosis, so typical of the after-effects of rheumatic endocarditis, which constituted nearly all the mitral cases in Calcutta as well as in London, is due to the extraordinary rarity of rheumatic endocarditis and pericarditis. In the London series the average age at death of the mitral stenosis cases was only 31.8 years, while in the case of aortic valve disease it was no less than 51 years, whereas the Calcutta series worked out from the 25 cases of mitral stenosis in 4,800 post-mortems in thirty-seven years, which was all there were to be found—although G. Samways reported no less than 70 in four years Guy's Hospital post-mortems—the average age was very nearly the same as in the aortic valve cases, namely, 30 years in the mitral and 32.3 years in the aortic cases—a very striking difference from the London data.

The average age of the London aortic cases is much higher than that of the Calcutta series. Out of the 25 London cases in which the age at death was recorded, no less than 14 were over 50 years of age, while none of the aortic cases in the last 600 Calcutta were over 50 years of age. This is a most significant difference, which indicates that the atheromatous disease producing aortic valve affections in Calcutta belongs to the syphilitic variety of middle age, while many of the London ones were of the later life degenerative type of atheroma, while syphilis is very common among the class of patients furnishing Calcutta autopsies. In 12 out of the 25 mitral stenosis cases in Calcutta, a greater or less degree of actual atheroma, usually of the aortic valves, was also present, while in no less than 87.8 per cent. of the fatal aortic valvular disease definite atheroma was found, in all but 15.8 per cent. of which it was of a marked or very marked degree, while in several of the mitral stenosis cases gummata were found also in the internal organs. Sir Leonard concludes that both aortic stenosis and regurgitation, and mitral stenosis in Calcutta are mainly, and probably very frequently, caused by syphilis.

Atheroma and aneurysms were nearly twice as frequent in the London as in the Calcutta series. The majority of the aneurysms in Bengalis occurred below the age of 41, and in London the majority were over 50 years of age, syphilis once more being the outstanding cause in Bengal, somewhat mitigated by the low blood-pressure of Indians, especially of the vegetarian Hindus.

From an analysis of 1,000 Calcutta cases and 300 London cases, there does not appear to be definite evidence of any material difference in the two series, and certainly no evidence of premature arterial degeneration in the Bengali race. In those over sixty years of a considerably higher percentage of the London series showed a marked degree of atheroma, but this is clearly due to there being many more elderly men in England.

Digestive Diseases.

The digestive system also presents differences of great interest.

Gastric and duodenal ulcers were twice as frequent in the London as in the Calcutta post-mortem; a figure which is below the truth on account of a larger proportion of operations having been undertaken for these conditions at St. Mary's Hospital, the unsuccessful cases appearing in the surgical post-mortems, which are not included in my tables, although they were twice as numerous, namely, 45 among 805 surgical cases, which bears out the general opinion that these diseases are less common in tropical races, although they are by no means very rare, and the exact causes of the difference are not known, although they have been attributed to differences in diet.

Others ..	3.3	2.16	0.2
Total ..	11.9	7.41	4.1

Enteritis, chiefly in children, shows 2.0 per mille in London against 1.42 in Calcutta, but this is largely due to the small number of children admitted to the latter hospitals, as the Calcutta vital statistics show that 4.1 per cent. of such deaths, even after omitting children under five, among whom they reached 6.1 per cent. of non-tropical diseases. Nevertheless, gastro-enteritis, apart from cholera and dysentery, is less common in Bengal than might have been expected in such a hot country with most defective hygiene and overcrowding, the explanation of which is doubtless the universal boiling of milk before use as an article of diet.

Cirrhosis of the liver remains to be discussed, and presents a most interesting and instructive subject. In a former analysis of 4,800 post-mortems, no less than 6.9 per cent. of cirrhosis cases were found, or seven times the rate in Germany, while the 1,600 Calcutta post-mortems show 5.91 per cent. after omission of the purely tropical diseases, as compared with 1.3 per cent. in the London records, or four and a half times as many in Bengal. This most remarkable difference cannot be explained on the still widely accepted alcoholic theory of its causation, so some other factor must be sought. This may possibly throw some light on the debatable point of its causation in Europe, where such an authority as Sir Humphry Rolleston considers that the rôle of alcohol has been over-estimated in the past, and that it acts as a predisposing cause of gastrointestinal catarrh, rather than as a direct exciting cause of cirrhosis, which it does not produce in animal experiments, while Sir Frederick Mott has pointed out that liver cirrhosis is not commonly met with in patients suffering from mental disease caused by chronic alcoholism.

Lieutenant-Colonel D. W. Sutherland, *r.s.s.*, has found the disease to be frequent among very strict Mahomedans in the Punjab, so there is no doubt that in India alcohol can be ruled out as a cause in a large proportion of the cases, for Mahomedans in Bengal only suffer slightly less from cirrhosis of the liver in proportion to their numbers than do the Hindus, while amebic abscess of the liver shows a very similar slightly lower rate in Mahomedans, although in this case alcohol is clearly not the exciting, but only a predisposing cause, in much the same way that some European authorities now regard it in the case of cirrhosis here. Moreover, cirrhosis was less common in proportion to their numbers in Europeans in Calcutta, although they generally take alcohol. The average age of the Calcutta cases of ordinary atrophic cirrhosis at death was 39.6 years, against 48 in Europe according to Rolleston, while Hindu males showed somewhat larger numbers than their normal proportion.

Of the 6.9 per cent. in the thirty-seven years' records 1.39 per cent. occurred in kala-azar, in which Sir Leonard described a special form of the disease excited by the presence of the Leishman-Donovan parasites in the endothelial lining of the hepatic capillaries, inducing what he has named an "intralobular" form of cirrhosis with delicate fibrous tissue bands throughout the liver lobule, producing a very hard, but smooth-surfaced organ, previously overlooked, but, in addition, many of the cases found complicating kala-azar are of the ordinary atrophic type. Secondly, we have a percentage of 0.12 due to "infantile cirrhosis of the liver" occurring in young children, apparently as the result of some dietetic or digestive errors. After deducting these

two varieties, although many of the kala-azar atrophic cirrhosis cases might fairly be included, there still remain 5.4 per cent. in the thirty-seven years' records, against 1.3 in the St. Mary's Hospital ones, or four times as many, in spite of the alcoholism being a very minor factor in its causation in Bengal, the reason for which requires careful consideration.

On tabulating all the complications of the cirrhosis cases, I found 25.6 per cent. of the fatal cases in which death was directly due to cirrhosis, and 30.1 per cent. of the latent cases, in which well-marked liver cirrhosis was found complicating other causes of death, dysentery had been present, usually in a chronic form or as scars of old dysenteric lesions. Granular kidney of some degree was also present in 13 per cent., the close relationship of these two diseases being well known, but no other complication was present in greater numbers in the cirrhosis cases than in the total cases. In 37.8 per cent. there was evidence of previous chronic gastrointestinal ulceration—after the omission of recent dysentery lesions—such as would be likely to result in long-continued absorption of toxic substances from the digestive system passing through the portal vessels to the liver. On the other hand, the percentage of the total cases, other than cirrhosis of the liver, showing chronic dysenteric lesions was only 8.86 per cent. or one-fourth as many as in the cirrhosis ones; so that it is likely that the causative factor in producing the great excess of cirrhosis cases in Bengal, in the absence of any material amount of alcoholism, must be toxic absorption through the portal circulation secondary to chronic forms of ulceration, nearly always of a dysenteric nature. Chronic forms of dysentery in the Calcutta post-mortems are mainly of the amebic type. Thus it is likely that the great frequency of cirrhosis of the liver in Bengal is antecedent chronic ulceration of the large bowel, usually of the amebic variety often of many years duration, and complicated by repeated attacks of hepatitis with great congestion of the liver due to the passage of the pathogenic ameba to the organ through the portal vein, which only occasionally goes on to liver abscess formation.

Urinary Diseases.

Kidney diseases are rather less frequent in Bengal with a rate of 6.35 per cent., against 8.6 per cent. in London, due to the slightly higher rate of 2.3 per cent. of parenchymatous nephritis in London to 1.96 in Calcutta, and the considerably greater number, 5.4 per cent., of granular kidney in England, against 3.46 in Bengal, which is easily accounted for on the age differences of the two series, as the disease increases in frequency with the duration of life in both countries, especially after 50 years of age. The remaining fatal urinary diseases of this medical series were few, and have a similar incidence in both areas.

Nervous Diseases.

Diseases of the nervous system show a greater preponderance in the English cases, due solely to the much larger number of cases of apoplexy, nearly all due to cerebral hæmorrhage, in the London series with four times as many subjects over the age of 50 years, which fully explains the difference in the figures.

Meningitis of non-tubercular varieties, however, were more numerous in Calcutta, with 3.29 per cent., than in London with 2.4 per cent., and that, too, in spite of the far smaller numbers of children in the Bengal series, so this is a real difference in the two climates, and one which is explainable on the ground already mentioned in connection with other diseases, namely, the frequency of infections due to the streptococcal group of organisms in hot moist Bengal with great overcrowding in the houses, for in 18 of 1,000 post-mortems where meningitis was the primary cause of death, 11 were due to pneumococcus, 2 more to streptococci, and 5 were tubercular. The striking preponderance of the pneumococcal cases is of interest in relation to the remarkable frequency of lobar pneumonia and pericarditis due to

this organism already mentioned, while cerebro-spinal meningitis is not very rare in India.

Tumours, Innocent and Malignant.

During the last few years a somewhat vague theory has been put forward that cancer (including in that term the malignant connective tissue sarcomata) is essentially a disease of civilised races, and that the alleged immunity of uncivilised people is due to their diet consisting of "natural foods" containing abundant vitamins, which are said to be deficient in the diet of civilised races, much of whose food is preserved by artificial methods and otherwise rendered deficient in those substances. The main basis of this theory rests essentially on the statements of its advocates that cancer is very rare among the more uncivilised races.

In 1,600 Calcutta cases, the rate is 4.59, as compared with 13.8 in the St. Mary's Hospital records.

Per cent. London cancer cases over 40 years of age	96.7
Per cent. London cancer cases over 50 years of age	76.0

Here, at first sight, we appear to have some confirmation of the alleged rarity of malignant tumours in the poor uncivilised races of India, who constitute the post-mortem subjects, but the very different age incidence of the Calcutta and London series necessitates corrections for that all-important factor. The London series show 4.8 times as many subjects over the age of 50 and 2.7 times as many over 40 years of age as the Calcutta series, while the total carcinomata are only 3.7 times as numerous as the Calcutta ones, although the London cancers showed 96.4 per cent. in persons over the age of 40, and 76 per cent. over 50 years of age. It is thus abundantly clear in the case of the carcinomata, the class of London malignant growths showing the greatest excess over the Calcutta figures, that the increase is fully explained by the several fold larger proportion of subjects of the cancer age in England as compared with Bengal; so we may conclude that these data, as far as they go, show no greater incidence of cancer in England than in India, when the age factor is taken into consideration.

An analysis of 1,190 tumours of which sections were cut in the pathological laboratory of the large Calcutta Medical College Hospital is given and the rates per mille of the principal forms of tumour are compared with those of 1,000 cases from the St. Mary's Hospital, London, pathological records.

The most striking fact is that in both series the malignant exceed the innocent tumours, and that the

percentage of malignant tumours is 57.9 in the Calcutta series, against 56.5 per cent. in the London one, the "uncivilised" races of India actually showing a higher proportion than the "civilised" people of England. The Calcutta percentage of sarcomata is 18.4 against only 9.1 per cent. in London, or one-half the Indian rate; while Calcutta showed 39.5 per cent. of epithelial malignant tumours against 47.4 in London, or five-sixths of the English figure, a difference easily accounted for by the 1921 Bengal census returns revealing only 17.86 per cent. of people over 40 years of age, against 27.53 in England, or only two-thirds of the British figure. The sarcomatous malignant tumours, with a much lower age incidence than carcinomata, are thus considerably more frequent in Bengal, while carcinomata are also relatively as frequent in Bengal in proportion to the population of the cancer age of over 40 years.

Incidence of the principal forms of innocent tumours.—Another striking feature is that the innocent connective tissue tumours form 24.45 per cent. of the whole in Calcutta, as compared with 14.7 per cent. in London, while, on the contrary, the innocent epithelial tumours numbered only 8.4 per cent. in India, against 15.8 per cent. in England, although the total number of innocent tumours were closely similar, namely, 42.1 per cent. in Calcutta to 43.5 per cent. in London. Thus, both innocent and malignant connective tissue tumours are commonest in India, while both classes of epithelial tumours preponderate in England, which supports the view of many pathologists with much experience of microscopical examinations of tumours, namely, that it is not by any means always easy to draw the line between simple and malignant growths, and that an innocent form may take on malignant characters at any time, simple connective tissue tumours becoming sarcomata and innocent epithelial ones carcinomata.

The innocent connective tissue tumours show a fairly general higher rate in the Indian figures, with the exception of fatty tumours, which are more numerous in the London series, probably due to this form of growth being practically harmless except for the disfigurement caused by them, resulting in the civilised race more frequently troubling to have them removed. On the other hand, about one-third of the total excess of the Calcutta figures in this group is due to the excess of myomatous tumours, 107 of 118 Calcutta, and 49 of 55 London ones having been tumours of the uterus, and the higher incidence in Calcutta is probably partly due to the special hospital for gynaecological and obstetric cases of the Calcutta Medical College Hospital having more beds than those of the St. Mary's Hospital wards for diseases of women, allowing of more numerous operations for this class of tumour. Nearly two-thirds of the Calcutta excess of simple connective tissue tumours, however, is due to the fibroma and fibromyxoma, for which there is no obvious explanation, while chondroma and osteoma were also slightly in excess in the tropical area; so we may conclude that the excess of this class of tumour as a whole in Calcutta is a genuine one.

The innocent epithelial tumours, were nearly twice as numerous in the London as in the Calcutta series, the excess being nearly equally marked in the two main classes of papillomata and adenomata. The adenomata were also nearly twice as frequent in the London series, but here the excess is solely due to 37 thyroid and 27 prostatic tumours, against 0 and 5 respectively in the Calcutta series; the thyroid excess, again being due to more frequent operations for this condition in London, doubtless often on account of disfigurement, which does not cause the coolie class in Bengal to desire or submit to operations for their common thyroid enlargements; while enlargement of the prostate is far rarer in the tropical area on account of the very much smaller percentage of elderly people liable to enlargement of this organ in Bengal. Adenomata of the breast numbered 31.9 per mille in Bengal against 23 in London, which is rather surprising in view of the great excess of cancers of this gland in London, although, if the cysts are added to the adenomata, the combined rate per mille London figure of 42 is in excess of the Calcutta one of 32.7, so that the total innocent tumour rate, including the cystic ones, of the breast is higher in the English series.

The sarcomata were met with twice as frequently in the Calcutta as in the London series, the excess which appears to be only partly accounted for by the larger proportion of persons of the younger decades in Bengal, for this class of malignant growth is met with at all ages. The very malignant small round-celled sarcoma greatly preponderates in the Calcutta series, the rate per mille being 110 against only 23 in the London series, while the proportion of the other varieties differs but little in the two series, although the melanotic form is also more common in the dark-skinned tropical race.

The malignant epithelial tumours or true cancers are nearly equally divided in both series between squamous and glandular epithelial forms, although the location of both classes differs widely in the two areas dealt with. There is little difference in the total number of the squamous-celled variety between the two series, but the glandular epithelial type shows a considerable excess in the London as compared with the Calcutta series, which is in accordance with the larger number of cancers in the London post-mortem data already dealt with, for nearly all the cancers met with in hospital post-mortems belong to the internal glandular carcinomata, which are far less easily diagnosed than surface tumours, and are thus less likely to be recognised in uncivilised races, with comparatively few well-qualified experienced medical men, in the absence of accurate post-mortem records and microscopical examinations, such as form the basis of my observations.

Distribution in the body of squamous epitheliomata.—Malignant growths of the skin are actually far more prevalent in the Calcutta than in the London series, namely, 50.8 per mille in the former, against 35 in the latter, and that, too, although the well-known Kangri burn epithelioma of the thighs and abdomen of Kashmir, due to carrying charcoal burners under the clothes in

that cold mountainous area, were not met with in Calcutta. This great prevalence of skin cancers in tropical Bengal appears to be associated with the common chronic forms of ulceration of the skin there seen, indicating that when chronic irritation is present, there will cancer be prevalent, as is so well illustrated by *Kangri* burn cancer itself, which E. F. Neve has recently reported affects principally the older men, the average age of onset being 55 years. In view of the considerably smaller proportion of the population of Bengal of the cancerous age, this excess of surface epithelial cancers is all the more striking and significant. Epithelioma of the lip was rather more common in the London series, namely, 11 per mille to 8.4 in Calcutta, while Calcutta shows 10.2 per mille cancers of the cheek against 8 per mille in London, the well-known form due to the irritation produced by chewing pan containing both lime and betel nut, being less frequently seen in Bengal than in Ceylon, for R. L. Spittel recently reported that he operated on about fifty a year in the Colombo General Hospital, although he is only one of three surgeons on the staff—once more illustrating that chronic irritation is at least as effective in originating squamous epitheliomata in the Eastern tropics as among civilised races of Europe and Northern America.

Cancer of the tongue and floor of the mouth was just over three times as frequent in London as in Calcutta, namely, 60, against 19.3 per mille, in striking contrast to that of the skin, the probable explanation of which is worth looking into. The three main recognised exciting or predisposing causes of this condition are syphilis, smoking, and the irritation of fragments of decayed teeth; but syphilis is at least as frequent, and probably more so, among the hospital class of patients in Bengal as in England, as judged by recent Wassermann tests carried out in the Serological Laboratory at the Calcutta School of Tropical Medicine, while smoking is also a frequent habit, although in excess it is probably less common in the tropical area, so these two factors taken together furnish no explanation of the great excess of cancer of the tongue in England. When we turn to the dental condition we find a very different state of affairs, for decayed and broken teeth are far more frequently seen in England than in Bengal; examinations of candidates of both races at the India Office during the last two years having shown me that a perfect set of teeth is as common in Indians as it is rare in Europeans of about the same ages. So here once more we find the explanation of the differences in cancer distribution in the two series of figures in chronic irritation being the most important factor in producing cancer, the frequency with which cancer of the tongue begins at the edge in contact with broken teeth being very significant.

Epithelioma involving the jaws were much more common in the Indian series, namely, 19.3 per mille against 9, which is probably associated with the great frequency of chronic pyorrhœa in the natives of Bengal, producing chronic irritation of the alveolar region; while cancer of the throat and larynx showed the reverse incidence with 4 in the Calcutta to 20 in the English series, which is much greater than is explainable by the age factor, and may possibly be related to excessive smoking irritating the delicate mucous membrane of the throat, or to innocent epithelial tumours of mucous membranes being more frequent in England. The œsophagus is also more affected by cancer in England than in Bengal, both in the tumour and in the post-mortem series, no such cases having been met with in the Calcutta post-mortems against 10 per mille in the London series.

Epithelioma of the penis shows more than twice as high a rate, 15.1 per mille in Calcutta, as in England with 7 per mille, and this is well known to surgeons in India and Ceylon. R. L. Spittel at the Colombo Hospital having operated on no less than 91 such cases within four years, and he, rightly in my opinion, attributes this great excess to the accumulation of smegma beneath a congenital phimosis, as he had never seen the

disease in circumcised races—yet, again, illustrating the importance of chronic irritation. On the other hand, epithelioma of the vulva and vagina were nearly equal, although those of the vulva were 4.2 in Calcutta to 1 per mille in London, while the figures of those of the vagina were reversed, namely, 0.8 to 3 per mille, but the numbers are too small to be of much significance. The London series included 28 per mille of secondary squamous epithelioma in glands, against none in Calcutta, although these were only included when not removed at the same time or nearly so as the main growth, indicating that in Calcutta patients seldom returned for such secondary recurrences, but for the inclusion of which the rate per mille of squamous epitheliomata would have been actually higher in the Bengal than in the English series, instead of very slightly less. We may therefore conclude that there is no difference in the incidence of this class of tumours in "uncivilised" Bengal people and in "civilised" Europeans in England, except that, when the age factor is allowed for, squamous-celled cancers are much more common in the Bengal race.

Distribution of glandular carcinomata.—This last class of malignant tumours shows rather larger numbers in the London series, although the distribution of various forms shows remarkable differences, which are of considerable interest.

Breast cancers numbered 152 per mille in London, against only 81 per mille in Calcutta; a remarkable difference which has been observed in other tropical countries. Fibro-adenoma of this gland is more frequent in the Calcutta series, but, if innocent cystic tumours are added, the number of non-malignant tumours is nearly equal in the two series; so the preponderance of cancers of the breast in England cannot be attributed to the frequency of innocent tumours becoming malignant, while it is doubtful if it can be fully accounted for by the age factor, so some other cause must be sought. It has been suggested that the custom of tight-lacing and wearing firm corsets in "civilised" races, now happily on the decrease in Western Europe, is an important exciting or predisposing factor in the production of breast cancer, and the complete absence of that habit among the little affected Indian women lends support to that view, so it is to be hoped that the more rational and hygienic fashions of the present moment may persist long enough to allow of its possible good effect on the incidence of this too common affliction to be thoroughly tested. As cancer of the breast is said to be common in unmarried women and in those who do not suckle their children, the rarity of such in India may also be a factor.

Cancers of the uterus and ovaries show extraordinary high rates in Bengal as compared with London, which is all the more remarkable when the age factor is taken into consideration. Thus, malignant growths of the ovaries were 23.5 per mille to 12 in London, or almost twice as many; cancer of the body of the uterus showed 45.4 against only 17 in London, or nearly three times as many, while that of the cervix uteri were 67.2 against only 18 per mille in the English series, or over three and a half times as high an incidence. A part of this very great excess in Calcutta must be attributed to the larger number of gynaecological beds in Calcutta Medical College Hospital as compared with St. Mary's Hospital in London, but after making allowance for that factor a great excess still remains, and that, too, although the age factor balances the hospital accommodation one, so the excess must be regarded as a real one requiring explanation, while its occurrence is also vouched for by Lieutenant-Colonel C. H. Leicester, I.M.S., now superintendent of the Women's Hospital of the Calcutta Medical College, and the reason must be sought for in the very different conditions of the child-bearing period in the two races. In the first place, the menstrual periods come on considerably earlier in Indian than in English girls, and still more important is the remarkably early age of marriage in India, where it is considered a religious crime for menstruation to take

place before marriage and co-habitation, so that active sexual life of females often begins at about 12 years of age, instead of probably over twenty on the average in England. Further, the climacteric, with involutionary changes in the genital organs predisposing to cancer development, is also considerably earlier in Bengalis than in Europeans in a temperate climate. Moreover, the age tables in Hoffman's valuable statistical work on "The mortality from cancer throughout the world" show that the cancer rate of the female generative organs rises greatly between 35 and 44 years of age, and still more rapidly in the following decade, especially in the cervical form which so greatly preponderates in Bengal, although that of the skin and large bowel shows no great rise until 55 to 65 in the United States; so that if cancer commonly occurs in India we might expect it to be clearly evident in the case of cancer of the uterus, as is actually the case, only much more so than the age factor alone will explain. We may therefore conclude that early marriage and the early ending of the child-bearing period of females in Bengal are important factors in the very high cancer incidence on the uterus and cervix; so that where the conditions are thus favourable this disease, so far from being only one-eighth as frequent as in European and North American races as Hoffman maintains, cancer is actually far more common in the "uncivilised" Indian race, even in spite of the age factor being so unfavourable to cancer in Bengal.

Cancer of the gastro-intestinal canal.—Here we meet with just the opposite position to the case of uterine cancers, for both gastric and intestinal cancer is much more common in the London than in the Calcutta series, as shown both by the post-mortem and the microscopical examinations of material from the hospitals, which are complementary, as the post-mortem data reveal the frequency of inoperable internal cancers, and the pathological laboratory reports those for the removal of which operations are commonly undertaken. Thus, gastric cancers formed 30 per mille of the St. Mary's Hospital post-mortems, against only 2.5 in the Calcutta autopsies, while in the microscopical reports the former showed 11 per mille against 5 per mille in Bengal, or not more than the age factor would account for. On the other hand, in the case of cancer of the large bowel the pathological reports showed 33 per mille in London, against only 7.6 in the Indian series, while the autopsy records gave 9 in London to 2 in Calcutta, and even this excess is below the true figure, for large bowel cancers were met with more frequently in the surgical post-mortems at St. Mary's than at Calcutta, which are not included in the analysis, and the same applies to oesophageal and, to a less extent, to gastric cancers, operations, other than for the relief of intestinal obstruction, having been more frequently performed in the London Hospital. These data fully confirm a very strong impression that cancer of the large bowel is a rare disease in Bengal as compared with England, the differences being considerably greater than can be explained by the age factor, in spite of the fact that no less than 23 of the 29 London gastric cancers of which the age was recorded were over 50, at which period the London autopsy series showed four times as many subjects as the Calcutta one.

This comparative rarity of gastro-intestinal cancer in "uncivilised" tropical races has been attributed by Sir Arbuthnot Lane to intestinal toxæmia secondary to constipation in "civilised" races. Some writers on cancer state that constipated stools are practically unknown in races living under primitive conditions on simple natural foods as in Bengal, but this is not correct, as Sir Leonard has met with constipated stools in Indian subjects post-mortem many scores of times in Calcutta. On the other hand, it is fact that such people, as a rule, pass soft unformed stools, and this is probably the most important cause of their relative immunity to cancer of the large bowel, but this is probably another example of the general rule that some form of chronic irritation is the most frequent precedent of cancer, and there

is no reason to attribute cancer here or elsewhere in the body to "intestinal toxæmia." With one noteworthy exception, the remaining forms of cancer, namely, those of the kidney and suprarenals, of the prostate and testicle and other miscellaneous varieties furnish very similar figures in the two countries dealt with, so that when the age factor is taken into account they are rather more prevalent among the vitamine-consuming more primitive Indian race. There only remain for consideration cancers of the liver and gall-bladder, which are of altogether exceptional interest, for the pathological laboratory data show 7.7 per mille of primary liver cancers and 5.4 per mille of cancers of the gall-bladder and ducts in the Calcutta series, against 0 and 3 per mille respectively in the London series—a most remarkable excess in the Bengali race, even without allowing for the age factor. In the post-mortem series Calcutta shows 5.7 per mille of primary cancer of the liver, against 2 per mille in London, while gall-bladder cancers numbered 9.4 per mille in Calcutta against 19 in London, the lower Bengal rate being more than explained by the age factor, for Sir Leonard finds that 14 out of 17 gall-bladder and duct cancers in the London post-mortems of which the ages are recorded were over 50 years of age, and all 17 were over 45.

Sir Leonard pointed out in his earlier paper that his data proved that the Indian hospital subjects, nearly all of the poorer coolie working class, showed the same feature that is well known in civilised races in Europe, namely, that gall-stones are considerably higher in each decade after the first, in females than in males, which is of interest in connection with the old European theory that this is due to females being addicted to tight-lacing and sedentary habits, neither of which are failings of the Indian coolie woman; another good example of the light that such a study as the present one may throw on questions of interest in European medicine.

Of much greater importance is the question of the incidence of gall-stones in India and in England in relation to the relative prevalence of cancer of the gall-bladder, and perhaps also of the liver, for it has been abundantly proved that gall-stones do excite the formation of cancer of this organ, while Dr. Leitch has demonstrated this experimentally in animals, so that we have here a crucial test as to whether the "uncivilised" races of India, living under primitive conditions on simple natural foods, are practically immune to cancer, as Hoffman and others claim when a cause is present which is known to excite the formation of cancer in the civilised races of Europe and North America living so largely on artificially prepared foods deprived of vitamins? The answer to this question is plainly written in the figures, for it will be seen that in every decade, from the second to the fifth, as well as in those over 60 years of age, gall-stones were more frequently met with in the Bengali race than in the English; while cancer of the gall-bladder is more common in the former than in the latter, especially in view of the much smaller proportion of the Bengalis living to the cancerous age. The disease is also relatively more frequent in females in proportion to their numbers in the hospitals than in males, and the pretty theory that vitamine-containing natural foods of "uncivilised" races protects from cancer once more completely breaks down when submitted to the practical test of carefully recorded and extensive pathological data.

Another point of especial interest is the frequency of the development of cancer in those who have gall-stones at different age periods.

Frequency of Cancer in Gall-Stone Cases at Different Age Periods.

AGES.	Gall-stone cases.		Gall-bladder or Duct Cancers.	
	No.	Per cent.	No.	Per cent.
Up to 30	.. 2	0.5	0	0.0
31 to 45	.. 12	4.6	0	0.0
46 to 50	.. 9	6.0	3	33.3
51 to 60	.. 25	10.7	2	8.0
61 to 70	.. 19	15.2	2	10.5
Over 70	.. 14	25.0	3	21.4

These data show that no cases of cancer of the biliary system arose before the age of 46, although gall-stones were common between 30 and 45; yet between 46 and 50 no less than one-third of the gall-stone cases developed cancer, although between 51 and 60 only 8 per cent. of such cases were complicated by malignant growths, and this proportion increased gradually in later decades, although not to as high a point as was reached between 46 and 50. 96.4 per cent. of all cancers in the London series, from which the above figures are taken, arose after the age of 40, mostly those of the fifth decade occurring in its second half; so that the sudden great rise in the gall-bladder and duct cancers, as soon as the age of 45 is passed, indicates strongly that it is only after that age that gall-stone irritation readily induces cancer formation in man, although most of the subjects had gall-stones during the previous decade. The advisability of removing gall-stones without delay in patients reaching the cancer age of 45 is therefore obvious. The data also lend striking support to the view that any increase in cancer during the last sixty years in Great Britain is mainly, if not entirely, due to the increase of about two decades in the average duration of life here during that period, as the result of great sanitary advances; being thus a penalty of increased longevity, requiring no theory of cancer being due to increased consumption of artificial foods to account for it.

The whole of the foregoing analysis of the incidence of malignant tumours in Bengal, therefore, may be summed up in the single sentence: Where the exciting cause is present, there will cancer result in primitive tropical people of the cancerous age at least as readily, if not more so, than in the civilised races of temperate climates.

Conclusions Regarding the Incidence of Tumours in Bengal and England.

1. Malignant tumours, including both connective tissue and epithelial types, are about equally common in Bengal and England, with a slight excess in the tropical country, quite contrary to the statements of those who maintain that civilised races suffer eight times as much from them as uncivilised primitive peoples.

2. Both innocent and malignant connective tissue tumours are considerably more common in Bengal than in England, while the reverse is the case with both innocent and malignant epithelial tumours; which supports the view that the innocent forms shade off into or may take on the characters of malignant ones.

3. The slightly lower incidence in Bengal of the malignant epithelial tumours or carcinomata is fully explained by the age factor, as the higher rate in London is more than accounted for by the great excess of persons of the cancer age of over 40 or 50 years in England as compared with Bengal.

4. Cancers of the tongue, œsophagus, stomach, large intestine, and breast show considerable excess in the London pathological examinations, while those of the skin, penis, both the cervix and body of the uterus, liver, and gall-bladder are in excess in India, nearly all of which are explainable on the known laws of long-continued irritation being the most important predisposing

or exciting cause of cancer. This relationship is strikingly illustrated by the figures given, showing that gall-stones and cancer of the gall-bladder are rather more common in Bengal than in London, for it has been proved experimentally that the presence of gall-stones may induce cancer formation in this viscus.

5. The three-fold excess of cancer of the uterus in Bengal is probably related to early menstruation, child-bearing, and menopause in the Bengali race leading to earlier and more frequent development of cancer in them as compared with European females.

6. In future, the onus will lie on those who proclaim the rarity of malignant growths in uncivilised races of proving their assertions by extensive and accurate pathological data, such as those on which the above conclusions are based, for about 90 per cent. of the Bengal population, who furnish a large proportion of the Calcutta hospital cases, live in villages under primitive conditions, and on a diet of natural foods.

THE CANCER PROBLEM.

By H. HALLILAY,

LIEUTENANT-COLONEL, I.M.S.,

Civil Surgeon, Simla.

Now that a full account of the research undertaken by Dr. W. E. Gye and Mr. J. E. Barnard on the "Ætiology of Malignant New Growths" is available, it is apparent that the cabled summaries of the results of the investigation which were published a few weeks ago if anything but underestimated their importance.

The *Lancet* in a long and thoughtfully written leading article hails the publication of this paper as a step towards the solution of the cancer problem.

By this mail we have received an endorsement of these results in an article specially written for the *British Medical Journal* by Dr. Archibald Leitch, whose high reputation as an original worker at the cancer problem and whose position as Head of the Cancer Research Institute at the Chelsea Cancer Hospital render him peculiarly fitted to express an opinion upon these the conclusions arrived at by the authors of this joint research.

There appears to be no doubt whatever that a real advance has been achieved towards the solution of the cancer problem. Continuing on the line of research which was started by Peyton Rous and abandoned by him 13 years ago, the authors have shown that not only is it possible to transmit the sarcoma with which he worked from chicken to chicken, by means of a cell-free filtrate, but that it is possible to reproduce the sarcoma in fowls by means of subcultures from the same cell-free filtrate down to the fifth subculture. Since the fifth subculture would entail a dilution of the original agent of a thousand billion times it is difficult to avoid the inference that growth of the original virus has taken place in the subcultures, because even in such low dilutions as 1/10th or 1/100th of the original cell-free filtrate in saline no growth follows inoculation.

They have shown, a very momentous and significant fact, that the cell-free filtrate contains two factors, and that in the absence of either factor no growth of the sarcoma will take place.

For instance it has been found possible to free the filtrate of all adherent material by washing in saline, and this washed filtrate does not produce any tumour when injected. It has further been found possible to render the virus in the cell-free filtrate innocuous by treatment with chloroform; this sterilised virus does not produce a tumour when inoculated. Injected together in sufficient quantity the combined factors invariably result in tumour formation.

In other words before this virus can implant itself in a living cell whether of man or animal, the presence of this factor, named by Dr. Gye the "specific factor" is essential. The "specific substance" is obtained or produced from the cells themselves presumably as the result of chronic irritation.

Oct., 1925.]

Though the virus itself is "ultra-microscopic" Mr. Barnard has been able to demonstrate it and even to take micro-photographs of it, by means of the special appliances which he has devised.

In short the authors are to be congratulated on the completion of a most brilliant and epoch-making piece of research, which not only brings us appreciably nearer to the solution of the cancer problem, but has opened up immense possibilities in many other fields of pathology.

Current Topics.

The Trend of Modern Hygiene.

By ANDREW BALFOUR.

Lancet, May 9, 1925, p. 1008.

Extracts from a paper read before the Royal Society of Arts on April 29th, 1925.

OF late years such a remarkable and far-reaching change has come over, both, the spirit of our dreams and our actual undertakings that we may, with some justice, assert that a new hygiene has been developed, a modern health campaign possessing features which entitle it to be classed as a distinct entity.

The most important item in the public health campaign is, beyond all doubt, education; not so much education of the medical student, the medical man, the dental surgeon, the veterinarian, or the sanitary inspector, as education of the lay public.

Dr. John Dill Robertson, of Chicago, does not hesitate to charge the general practitioner with criminal negligence, hoping that his message will prove so irritating that it will stimulate him to a sense of his responsibilities as a guardian of the public health in his own special direction. According to Robertson, who, of course, merely voices in rather a strident tone the views of others, the true function of the private practitioner is not to cure the sick, but so to advise his patients, or rather, his clients, that they will remain in good health. Away back in 1907 the same argument was advanced as forcibly by Dr. John McVail in a memorandum accompanying his report on Poor-law Medical Relief in England and Wales. In a recent address he developed his theme and indicated seven directions in which the family physician might be of service as a valuable ally of the medical officer of health.

He deals with the doctor as a historian, an inquirer into family history, and as an observer and checker of tendencies towards general disease. Let it be noted that amongst the diseases mentioned figure obesity and alcoholism. He envisages the physician as a health guardian of the child, a watchful attendant both of mind and body, a corrector and remover of defects, an adviser to the parents. He traces the extension of this medical care to the youth and the maiden, when the practitioner should guide as to work and athletics and be upon the qui vive to remedy faulty tendencies of all kinds at the threshold of adult life. He pictures him as the friend and confidant of the woman, saving her from the special troubles besetting her sex, and watching the adult man, to see that he does not develop some trade disease, strain his heart, or damage his respiratory organs. In addition, he speaks of general examinations like those for which Dr. Robertson pleads, and he figures the doctor as a prop for old age, trying to ward off apoplexy and stay the morbid processes which too often make the evening of life a tragic misery. Dr. McVail is careful to point out that the doctor can only assume such a rôle with the consent of the individual—the adult for himself, the parent for the children.

Now while, presumably, the majority of medical men at the present time could be trusted to give a sound

opinion on the middle-aged golfer, it is by no means so certain that they could adequately fulfil the duties listed by Dr. McVail. They have been reared, he it is remembered, in an atmosphere of curative medicine, and they have not been trained to look for the beginnings of disease. Of course, amongst them there may be a few James Mackenzies with the seeing eye and the understanding heart, but, taken as a whole, the general practitioner is a patcher, not a preventer. That is not his fault. In the past his training has been defective.

For one thing, he has struggled through a series of more or less water-tight compartments. There has been little linking up of his early scientific knowledge with his later medical and surgical studies, and, if he is to act effectively, his medicine and surgery must be leavened with a leaven wherein physics, chemistry, biology, anatomy, and physiology are combined as ingredients, together with sympathy and common-sense. For another, the doctor, as a student, has been so crammed that too often one mass of ill-digested facts has, throughout the curriculum, crowded out another in process of assimilation, and the only wonder is that he has emerged sane and sound and with a modicum of useful knowledge. For yet another, the preventive aspects of his life's work have not been explained to him, and the vast possibilities which lie before him are too often as a sealed book.

Now all this is changing. The beginnings of that change are recounted in the masterly treatise by our distinguished chairman, his memorandum entitled "Recent Advances in Medical Education in England," or, as he might have written, "Great Britain," for he cites Scotland again and again, and the old Alma Mater which I had the honour to share with him. Sir George Newman and others have remembered what happens when the blind have blind leaders and by degrees a new type of doctors should be evolved, who, it is to be hoped, will combine the acumen of the old clinical observer with the broad outlook of the sane scientist.

One of the most significant happenings in the modern health campaign is the attention paid, not only to dietetics, but to food preservatives and to the handling of food-stuffs. The layman, I fear, must be a little bewildered by all that is said and written about diet. Screeed succeeds screeed on vitamins. Here an authority thunders against butchers' meat and starchy foods, there an oracle condemns milk for adults. We read of human cesspools. We are told that our faulty food habits explain the increase of cancer. At times one wonders how the human race has managed to survive at all and exclaims with Pontius Pilate, "What is Truth?" And yet we are progressing, for we are beginning to understand the relation of diet to endocrine secretion and we are correcting errors into which we have drifted through non-adaptation to our complex surroundings, through failure to understand that what the primitive man can do with impunity the civilised man, or at least the town-dweller, does at his peril. The truth really lies in moderation, for, in a phrase I once coined and which perhaps will bear repetition, it is still the case that many folk by their copious libations 'wash themselves into graves which may have been dug with their own teeth.' Copious libations do not signify wholly, or even mainly, the imbibition of alcoholic beverages, for a vast deal of digestive trouble is brought about by excess in tea and coffee drinking, and by the swilling of liquid, frequently in effervescing form, during meals. Most of us after middle-age eat far more than we require. War experience should have taught us a salutary lesson, but, like other lessons, it has been forgotten.

I am inclined to think that eventually the chief value of the scientific tirade on foods and feeding will be found to lie in the fact that it will teach some sections of the most important class of the community—the workers—how to live cheaply as well as healthily, how to get the best food value for money spent. This in itself is a great matter, for the waste at present is enormous. Remember, however, there are many poor

housewives who, on the practical side could give the scientist points.

The conditions in a country like India are such that I sometimes think it would be well if the practice of hygiene there and in some other lands assumed the aspect of religious exercises. There are many forms of worship inferior to that of the goddess Hygeia, and if only the devotions could be adapted to the mentality and habits of the people, I believe more benefit would accrue than from all the efforts now made.

In Africa the case is rather different, and at the present time a great effort is being made to educate the African along sound lines. The trend is towards creating native hygienists who will be able to aid in the sanitary salvation of the Dark Continent. I have no doubt, from what I have seen, that this is capable of accomplishment, though it will take time and money. What the Americans call "visual education" is badly needed, and whether this be accomplished by the cinematograph, by diagrams and models in the schools, or by the establishment of graphic museums, care should be taken that it is not neglected in any scheme for native training.

The Future.

Lastly, both at home and abroad, stress should be laid on the financial aspect of public health work, and the ultimate aim of the hygienist should be clearly and definitely stated. The monetary value of sanitary endeavour is a very tangible thing, and statistics are now available regarding many lines of health work, which are most impressive and should convince all save the cranks and the wilfully ignorant. Thus, taking industry, which is so closely related to finance, we know, beyond all manner of doubt, that attention to mental hygiene in factories and workshops promotes harmony and leads directly to a larger output.

A hopeful sign is that there is much enthusiasm and no little idealism in public health circles, and, so long as these are well regulated, they cannot fail of their effect. Yet it is wise to bear ever in mind the dictum of Rienzi and the wisdom of Adam Smith. Rienzi wrote: "The prudent man may direct a state, but it is the enthusiast who regenerates it or ruins;" while Adam Smith, in his "Wealth of Nations," before the dawn of the so-called scientific era, declared: "Science is the great antidote to the poison of enthusiasm and superstition."

The Specific Action of Drugs in Tuberculosis.

By W. E. DIXON, M.D., F.R.S.

British Med. Jl., May 2, 1925, p. 813.

It is now well recognised that a patient suffering from tuberculosis, who is placed under the charge of a doctor will, for a time at least, improve in health no matter what drugs, vaccines, or speciality of treatment may be employed. The beneficial result is due in this as in other diseases, to efficient nursing, to the regulation of food, exercise, and sleep, and to light and fresh air.

General hygienic measures are of primary importance in treatment, and it is not until all the beneficial effects, which we know will ensue from these alone, have been exhausted that we have any right to ascribe an effect, beneficent or otherwise, to a special treatment.

Drugs are employed in tuberculosis either with the object of attacking and preventing the growth of the tubercle bacillus or other organisms with which the disease may be associated, or of neutralizing poisonous toxins, or of removing or relieving symptoms. It is with the first group that Dr. Dixon deals in this address.

The ideal for which we search is an internal antiseptic something which will prevent the growth of the tubercle bacillus without injuring the host, and this principle of internal antiseptics has now come to be termed "chemotherapy."

The ordinary common antiseptics, like phenol and the coal-tar derivatives (cresol, guaiacol)—mercury perchloride and formalin, destroy the animal before they destroy bacteria.

If the coal-tar derivatives (cinnamic acid, creosote, guaiacol, and the rest) exert a beneficial action on tuberculous patients, the explanation is not that they influence directly the tubercle bacillus. The same is, of course, true of formic aldehyde, at one time much in vogue as a vapour for inhalation by phthisical patients. Formic aldehyde in the body at once combines with proteins and loses all antiseptic action.

Essential-oils, like oil of cinnamon and oil of garlic, fail in the hands of the sceptical physician. Fischer showed that menthol-eucalyptol injections into tuberculous rabbits in no way altered the course of the disease.

Calcium.

Maendl treated 250 patients with intravenous injections of 5 c.c. 10-per cent. calcium chloride every day or second day. The injections were given on alternate weeks, and each patient received twenty injections. All the symptoms were influenced favourably. Calcium deficiency is a well-known condition of many diseases, including tuberculosis, and calcium injections may influence favourably the condition by limiting inflammatory exudation, but they do not influence the cause of the condition.

Silica has not been proved to be of any value.

Arsenic.

Inhalation of arsenic has been described as effecting cures by Chavant. On the other hand, careful experiments made with the likely organic arsenic derivatives such as arsphenamine and its silver compounds show that they have no favourable influence on the disease.

Chemotherapeutic agents have a specific selective action on certain tissues and bacteria, probably physical rather than chemical, and, unlike the group we have considered up to now, their disinfectant action is not retarded by admixture with serum, but on the contrary, is increased.

Two groups of organic compounds are specially remarkable for their chemotherapeutic action on bacteria. Quinine is the methyl ether of cupreine, and it can be reduced by nascent hydrogen to form hydrocupreine. The following table shows the effect of two derivatives of hydrocupreine in arresting the growth of certain micro-organisms.

	Ethyl Hydrocupreine (Optoquin).	Iso-octyl Hydrocupreine (Vuzin).
Diphtheria ..	1 in 100,000	1 in 750,000
Pneumococcus ..	1 in 400,000	Negligible
Staphylococcus ..	1 in 500	1 in 16,000
Streptococcus ..	1 in 1,000	1 in 80,400

The action of optoquin on the pneumococcus and of action on bacteria are certain derivatives of acridine. and lower homologues do not exhibit this effect. Further, these drugs act in the animal body as well as in the test tube, and enough can be given by medicinal doses to animals and men to clear the blood from these micro-organisms.

Acridine Derivatives.

The second group of drugs which exert a marked action on bacteria are certain derivatives of acridine. Trypaflavine was used during the war, for infected wounds; it acts better in the presence of protein, but is not sufficiently selective or specific on micro-organisms in the presence of body tissues to be of any real value; it is easily absorbed and causes oedema. Rivanol is a

more recent derivative of acridine. Morgenroth cured streptococcal infections in mice by injections of rivanol under the skin. The injections, to be efficient, must be made soon after infection and in the neighbourhood of the inoculated zone; rivanol will not cure a blood infection.

The chemotherapeutical substances which are known to act on bacteria are without value in tuberculosis. The destruction of the tubercle bacillus presents two special difficulties: (1) in the fatty and protective envelope surrounding the bacillus, and (2) in the small blood supply to the tuberculous lesions.

Cerium.

Success, however, has been claimed for several metallic compounds, and I shall confine my remarks to three of these. The first is with cerium salts. (Frouin experimented with fifty rabbits and thirty guinea-pigs; they were inoculated with bovine tuberculosis and treated by injections of cerium sulphate. All the animals died, treated as well as controls, but the treated animals survived from two to five months longer than the controls, and in post-mortem examinations showed considerable growth of fibrous tissue in the tuberculous lesions. Grenet and Drouin tried the effects of cerium earths in chronic tuberculous affections in patients. They state that two facts have been established—that these metals reduce the fats of the tubercle bacillus in cultures, and that they produce a mononuclear leucocytosis. Their procedure is to inject intravenously 2 to 5 c.cm. of a 2 per cent. solution for twenty days; this is succeeded by a period of rest for fifteen or twenty days, followed by a second and third series of injections. The patients improved in every way. The bacilli disappeared from the sputum, or if present were modified.)

The treatment is of value only in afebrile cases.

The evidence so far presented is of little real significance.

Copper.

Copper salts have had a great boom in the past. Graf v. Linden in Germany produced a complex copper lecithin compound of secret composition; it was alleged to produce wonderful results in the treatment of patients. It is now more than twelve years since the introduction of this compound, and yet there is an alarming spread of tuberculosis in Germany, and since the war we hear little of the cure. Koga, in Japan, produced cyanocuprol as a cure, but Koga's discovery has not settled the tuberculosis problem in Japan.

When the copper treatment commenced nearly all the reports were favourable to its use (Meissen, Strauss, etc.), but more extended investigations on animals made with the sulphate, oleate, albuminates, cyanocuprol and others have established the fact that so far as these salts are concerned the treatment, at all events on animals, is valueless.

The copper treatment of tuberculosis is not considered to be a specific therapy.

Gold.

Koch showed that $KAuCy_2$ (1 in 1,000,000) prevented the growth of tubercle in cultures; the presence of blood serum interfered with the action and reduced the efficiency to 1 in 25,000.

The results of administering gold salts in tuberculosis were not better than those given by copper, whether on cultures of the tubercle bacillus, on tuberculous animals, or on patients.

Aurocantan was soon found to be too toxic for use, it was succeeded by "krysolgan," introduced by Feldt. Nevertheless, animal experiments with this substance are not very promising, though clinical results, as published in Feldt's monograph in 1923, are certainly both hopeful and inspiring.

The last of the gold cures is that recently introduced by Moellgaard. It is a double thiosulphate of gold and sodium, $Au(S_2O_3)_2Na_2$, which, although a well recognized substance, he calls sanocrysin. Moellgaard

assumes that his gold injections destroy the tubercle bacillus *in vivo*, and states that doses which are not poisonous in themselves kill the tuberculous animal by producing a tuberculin shock. This shock begins with albuminuria and sometimes hæmaturia; it is followed by toxic myocarditis and pulmonary oedema. Non-tuberculous animals do not exhibit this shock.

To combat this shock Moellgaard recommends a previous injection of antitoxic serum, after which his gold cure may be injected with impunity. It would be interesting to know whether other metallic poisons cause a like shock.

Moellgaard made many experiments on calves, rabbits, and other animals to test his sanocrysin, and the treated calves certainly did better than the controls, and some of them recovered. His procedure was as follows: He injected a number of animals on the same occasion; after some days the animal which seemed least affected was chosen as a control. Dr. A. S. Griffith thinks that this was wrong, since the calves may have been infected before they were used for experiment. The injection of the tubercle bacillus would cause those which had acquired some increase of resisting power as the result of a spontaneous infection to react violently for perhaps a week, while the really susceptible animals would remain unaffected; one of the latter would be selected as the control. It is true Moellgaard made tuberculin tests when the animals were three weeks old, but their weights show that they were much older when injected. The experiments of Dr. L. Cobbett at Stansted under the Royal Commission showed that, in spite of ideal conditions and constant care, it was impossible to exclude spontaneous infection.

Another feature of importance in these experiments is that the cultures used were attenuated. The doses necessary to kill were enormous and many control animals failed to die or contract severe disease. The attenuation of the bacilli makes recovery much easier and the large size of the dose intensifies the severity of the reaction to injection in an animal already infected.

So far as I am able to judge of the value of the recorded experiments, they are suggestive, but certainly not conclusive. Some of the krysolgan and copper experiments on animals have been equally suggestive, and with regard to the patients it is early to draw conclusions; it is the opinion of those best able to judge that clinical records of treated patients must be kept for years before the true value of a remedy for tuberculosis can be gauged.

Sanocrysin, then, is still on its trial.

The Sanocrysin Treatment of Tuberculosis.

GREAT claims have been made for the sanocrysin treatment of tuberculosis and so it is necessary that the practitioner should be in a position to form an opinion as to the value of the new remedy. For this reason we reproduce some extracts from Professor Moellgaard's article in the *British Medical Journal* of April 4th, 1925 and also from the report of the Medical Research Council which has been making an investigation of the treatment.

The impression that is formed is that the treatment is no more likely to effect a revolution in the treatment of tuberculosis than the numerous "cures" which have been introduced during the past half century.

Although chemical substances have been employed to a very large extent in the treatment of tuberculosis no real chemotherapy of this disease has hitherto been developed.

To kill and dissolve bacilli in an organism by means of a bactericidal substance very often has the same effect as to inject killed or avirulent cultures—that is, it has an immunizing effect. The injection of the bactericidal substance produces an "ictus immunicatorius" (Ehrlich). Hence chemotherapy not only means bactericidal treatment, but also indirect immunization with liberated antigen. It may, however, under certain

conditions produce another indirect effect. If the antigen is very toxic or is liberated in very large amounts, or the capacity of the organism for building antibodies for one reason or another is diminished, the injection of the bactericidal substance produces a more or less grave toxæmia, increasing in some cases to a deadly effect.

The natural reaction of the therapist to this is to diminish the dose of the bactericidal substance. It must, however, be clearly understood that the effect not only depends on the quantity of the dose, but also on the amount of easily influenceable bacilli in the organism; further experience of chemotherapy has shown us that minimal doses are not only without effect, but in some cases even stimulate the disease ("effectus contrarius"—Ehrlich). Reduction of the dose, therefore, does not always solve the question of toxæmia. Where this effect is prominent chemotherapeutic treatment can hardly be carried through without the help of an active or passive immunization of the infected organism against the liberated toxins. In these cases clinical treatment must be carried out as a combined chemo- and sero-therapeutical treatment.

Krysolgan seems only to have a detoxicating effect in certain cases of pulmonary tuberculosis and to cause quick healing in some cases of localized tuberculosis.

In tuberculosis the question is complicated by two peculiarities in its pathology.

1. The specific resistance of the bacillus of Koch is due to its content of fatty substances, whose presence is the principal reason for the so-called acid-fastness of the bacillus and its resistance to antiformin and other generally employed disinfectants. A bactericidal effect of any compound of a heavy metal on tubercle bacilli is, therefore, not to be anticipated, except subject to the condition that the compound is capable of penetrating the fatty system and so carrying the metal into the body of the bacilli.

2. The peculiarity of the tuberculous tissue, which is of importance in chemotherapy, is its poverty in vessels. This means that a chemical compound must diffuse from the blood through the tissue to reach the tubercle bacilli, and the distance through which diffusion must take place grows longer as the tubercle increases in size and develops in caseification. The hope for chemotherapy in tuberculosis is therefore probably intimately connected with the possibility of finding a substance which diffuses very quickly through animal membranes, and which is sufficiently stable in the organism to be kept unaltered in the blood and the lymph for a relatively long time.

So far sanocrysin appears to be the body which best fulfils this condition.

From animal experiments it appears that sanocrysin in doses of from 1 to 4 cg. per kilo of body weight has very little effect on the sound organism. The weak point in the pharmacology of the substance is its action on the kidneys. This action is, however, avoided when the initial dose does not exceed 1 cg. per kilo nor the maximum therapeutical dose 2 cg. per kilo. Most animals endure bigger doses, and clinical experience has shown that the same is true in a large number of human beings.

On the other hand, the effect on the kidneys seems to be quickly reparable. Even with doses up to 6 cg. the albuminuria disappeared in a few days, and we have never found the lesions of the kidneys to develop in calves into chronic nephritis—even after six months' observation.

A chemical compound which kills tubercle bacilli in the organism will probably cause very serious toxæmia when injected into a tuberculous organism.

The investigations of Koch showed that the healthy and the tuberculous organism react quite differently to the injection of killed tubercle bacilli or tuberculin. In the healthy animal the toxic effect is produced only by large doses of killed tubercle bacilli and takes a relatively long time to develop. Even very small doses of killed bacilli or tuberculin often, in tuberculous animals, cause

very severe symptoms, which develop in a relatively short time, and are signs of an acute intoxication of the organism.

One-third of the sanocrysin dose which is tolerated by the healthy guinea-pig always produces very severe intoxication in the highly tuberculous guinea-pig, and usually kills the animal in sixteen to forty-eight hours.

In tuberculous calves which ordinarily do not die until forty-eight hours after the injection of sanocrysin, the development of the shock, was investigated in detail. Ordinarily it begins with albuminuria, which develops into a grave parenchymatous nephritis. Shortly after the appearance of the grave symptoms of nephritis (increasing albuminuria, cylindrical casts and blood corpuscles in the urine) acute myocarditis appears. The third and last stage in the intoxication in animals affected with pulmonary tuberculosis is an extensive œdema of the lungs, which increases until the animals die, with frothy fluid exuding from the mouth and nose.

Serotherapy of Sanocrysin Shock.

Serum from a calf, affected with chronic tuberculosis for about three months, was given intravenously into two tuberculous calves suffering from grave shock produced by a sanocrysin injection. The result was striking; these calves recovered clinically in a few hours, and the albuminuria disappeared in twenty-four hours. This observation suggested that it might be possible to immunize animals against shock.

A serum was first produced in calves by repeated injections of killed tubercle bacilli and tuberculin. At present it is made by injection of defatted, formalin-treated tubercle bacilli, according to Dreyer's principle. By means of this antigen the strength of the serum has been increased, and it has been possible to make it in horses.

With this serum forty tuberculous calves and goats, suffering from albuminuria after sanocrysin injection, have been treated on more than 120 occasions. In all cases where the infection has been reasonable the albuminuria has disappeared, in most cases very quickly, but in some more slowly, and the shock was totally prevented.

Sanocrysin in tuberculous animals and human beings can produce an acute intoxication, which does not occur when much larger doses are injected into healthy animals, and this intoxication can be prevented or cured by means of a serum made by immunization of healthy calves and horses with defatted formalin-treated tubercle bacilli. Consequently it is possible to confer upon tuberculous animals and human beings a specific immunity against the lethal effect of sanocrysin. This is probably the best proof of the bactericidal influence of this substance upon tubercle bacilli.

Animals with a more chronic tuberculosis very often show a high immunity to shock, and the same is true with certain tuberculous human beings. These animals or patients tolerate the sanocrysin injection without getting any albuminuria or other signs of the shock.

The tuberculous organism, whether naturally immune or made immune by serum, gives very pronounced reactions to sanocrysin, but of another very different type. None of the features of shock appear, but we find instead all the symptoms belonging to the second group mentioned above—the "tuberculous reactions." The most obvious of them are:—rise in temperature, exanthemata, loss in weight, faintness, and intestinal disturbances. Besides them focal reactions in the infected organs are observed with more or less regularity, as happens with tuberculin injections.

One important feature of all the reactions mentioned must be emphasized: they all disappear gradually as the clinical signs of the disease disappear. This fact is very interesting, because it is just what might be expected if sanocrysin is really able to cure tuberculous disease.

Before their total disappearance the reactions to sanocrysin are ordinarily delayed until two or three days after injection. The transitory stage between the disappearance of the clinical signs of tuberculosis in the

lungs and the definite loss of reactions is marked by "late reactions."

In experiments the late reaction has been found only in the last stages of the cure. Where, however, the bacilli are well protected by fibrous tissue (a condition present in many cases of chronic tuberculosis met with clinically), delayed reactions are to be expected from the beginning of the treatment. Clinical experience has shown that "late reactions" two to four days after a sanocrysin injection very often occur.

For the clinician it is of great importance to know that even big reactions may occur as late as four days after one sanocrysin injection, because it tells him that if he injects a fresh dose within this interval he may bring upon his patient the risk of a cumulative effect of the liberated toxins.

The combined sanocrysin-serum treatment has saved the life of even very gravely infected goats, calves, and monkeys, and brought them into a condition of clinical healing. On the other hand, it appears evident from the experiments that a thorough sterilization of the affected organs is very difficult and probably very seldom secured in cases of grave infections.

The best effect of the sanocrysin-serum treatment in the human subject will be obtained in cases of the exudative pneumonic type. Clinical experience seems already to show that this consideration comprises a true idea, the most striking clinical results having been secured in exudative cases.

As was to be expected, the extent and gravity of the tuberculous process set a certain limit for the success of the sanocrysin treatment.

Animal experiments have shown that other diseases in the lungs (mixed infections) may render it very difficult to obtain a curative effect with sanocrysin because the other processes themselves progress or protect the tubercle bacilli against the substance by enclosing them in large sclerotic masses of destroyed tissue. This has been observed in goats gravely infected in both lungs with *Strongylus capillaris* as well as with tuberculosis.

THE FATE OF THE TUBERCLE BACILLI IN THE TISSUE AND THE ALTERATIONS OF THE TUBERCULOUS LESIONS.

In three cases after two to four weeks' sanocrysin-serum treatment, microscopical examination of preparations stained by the Ziehl-Neelsen method showed, particularly in small remaining military tubercles and their surroundings, numerous acid-fast granulations mixed with curled acid-fast and grey non-acid-fast bacilli.

The Gold Treatment of Tuberculosis.

• *British Med. J.*, April 18, 1925, p. 735.

So much interest has been aroused by the claims made for Moellgaard's gold treatment that the preliminary report by the Medical Research Council will be heartily welcomed by the medical profession. We give extracts from this report.

"Various gold compounds have from time to time been used in the treatment of tuberculosis. Recently a soluble complex salt of gold and sodium—namely, sodium auri-thio-sulphate, which has long been known to chemists, and is now made available under the trade mark of "sanocrysin"—has been introduced to therapeutics as a treatment for tuberculosis, by Professor Moellgaard of Copenhagen, who has found that it has the advantage of dissociation into complex ions, so that toxicity due to free gold ions is avoided. Such toxic effects as this compound produces in tuberculous but not in normal subjects are attributed to destruction of the bacilli and increased liberation of tubercle toxins; and Professor Moellgaard has also prepared an antitoxic serum for use, when necessary, to counteract these ill effects. The results of experiments on animals and of numerous trials on human patients in some Danish hospitals have been fully described in his book on the *Chemotherapy of Tuberculosis* (autumn,

1924). Critical summaries of these results and of other work in Denmark have been published recently in the *British Medical Journal* and in the *Lancet*. Clinical trials are now proceeding also in Germany and in Canada.

Professor Moellgaard very courteously gave to the Medical Research Council a full supply, both, of the gold salt and of the protective serum, for clinical trial in England, but desired that the preparations should not be made available for general use in medicine until the results of these trials were completed. In December he and his chief clinical colleague, Dr. Secker, visited England, and made a personal communication on the subject to those who were asked to try the preparations; while Dr. Secker remained in London long enough to visit several hospitals, advise on the selection of cases, and give the observers invaluable help during the treatment of individual patients by instruction drawn from his own wide experience.

The preparations were issued by the Council, as on the similar occasion of the introduction of insulin to therapeutics, only to those who were not engaged in private practice—that is, to whole-time professors of medicine or to tuberculosis officers. The Ministry of Health was kept in close touch with the work through a liaison officer. On account of the general interest aroused by discussion of this method of treatment, the Council thinks it desirable to issue this preliminary report on the early results of cases so far treated in Great Britain, and to explain its further policy.

Work in England has been in progress for less than three months; it has not been on a large scale, but the value of the opinions formed has been enhanced by the arrangement which used several observers of small groups working at first independently of each other rather than one observer of a large group. It was evident, when the observers subsequently met in the first conference upon which this report is based, that there was so great a divergence of opinion upon the value of the drug that any single observer, relying solely on his own experience, might easily have been led to a summary opinion that would have been unduly emphatic in his judgment for or against the treatment. The report deals solely with clinical results, and does not consider the laboratory evidence for the effect of the gold salt on tubercle bacilli or infected tissues, nor that for the protective action of the specific serum.

Each dose of sanocrysin was dissolved in 10 c.cm. of distilled water and injected intravenously. The usual amount was 0.5 g. for the first injection and then repeated injections of 1 g. each at intervals of about three days, unless a severe reaction on the part of the patient occurred and compelled delay until the reaction had subsided. The total amount used in any case was generally about 5 or 6 g., and the injections were rarely continued until the goal suggested by the Danish experiences was attained—namely, a final state in which the last injection produced no rise of temperature.

The specific serum, usually from horses immunized by diaplyte tubercle vaccine, though at first a weaker calf serum also received trial, was injected into the muscles in doses of 20 c.cm. Its action is supposed to be that of neutralizing the flood of tuberculous toxins liberated by the action of the gold salt on the infected tissues, and thus of lessening the general severity of the reaction to the chemotherapeutic injection. In cases with heavy tuberculous infection the serum was used either before or together with the first gold injection as a preliminary measure. In mild cases it was not used until a reaction of some severity had occurred, and in many instances it was never used at all.

Effect of Injection of Sanocrysin.

Vomiting was often noticed as an immediate effect within a few minutes of the injection. In one control patient, without evidence of tuberculous disease, there was nausea and prolonged anorexia after three injections, but no rise of temperature or any other reaction. There were no other control observations of cases with

fever from known causes other than tuberculosis, so that the evidence is not sufficient to ascertain whether the gold salt can be used as a test to distinguish non-tuberculous from tuberculous febrile states. In a group of five cases of pulmonary tuberculosis that were clinically mild but radiologically moderately extensive, there were slight pyrexia and trifling albuminuria, but no other features of reaction. The gold salt in amounts up to 5 or 6 g. therefore seemed to be non-toxic for patients with only slight tuberculous lesions.

Severe reactions were generally produced in cases of more extensive infection. The temperature rose within a few hours to 103° or 104°; but there was no case of hyperpyrexia or of critical fall. Vomiting often recurred, but diarrhoea was not often observed. The patient felt ill, depressed, and lost appetite. A metallic taste was sometimes complained of, and there was a tendency to ulceration of the mouth and throat. The rise of temperature lasted three or four days, but was generally less with each successive dose. After the second or third dose rashes often appeared, like those of measles or scarlet fever, and not often itching. In one case an erythematous rash persisted for a fortnight and was accompanied by an outbreak of many indolent open sores. The rashes were seen in cases where no serum had been given. They were perhaps more frequent in cases of closed tuberculous infection.

Albuminuria was a common occurrence, and in some cases exceeded 1 per cent. though it did not last long. No oedema resulted and there was no evidence of persistent renal lesions. Measurements of blood urea were not made in any of the cases of severe albuminuria. In one necropsy, where there had never been more than trifling albuminuria, 8 per cent. of the total metallic gold injected was found in the kidneys on death twenty-eight days after the last injection of sanocrysin. Gold was proved to be excreted by the bowels and by the kidneys after an injection of sanocrysin. Jaundice of a grave nature, which in the Danish experience was a very rare event, occurred in another patient who died, and a relatively large amount of gold was found on analysis of the liver.

Features strongly suggesting that the gold salt had a direct action at the site of the tuberculous infection were often seen. Thus, in the lungs a focal reaction was evidenced by local pain, a sense of tightness, and by prolonged tachypnoea. This was in at least three instances aggravated by the development of a very critical state in which the pulse became rapid and feeble and the patient so collapsed, though the temperature did not fall seriously, that great anxiety was aroused as to the chances of recovery. Except for a local increase of crepitant râles, there were no clear changes in the physical signs in the lungs during these focal reactions. Cough, however, was generally increased and sputum was at first more abundant if the patient had strength for expectoration. Subsequently both cough and sputum tended to lessen.

Headache was never intense. A general state of depression and lack of vitality, together with loss of weight, tended to develop in cases of extensive infection after a course of treatment, and this retarded subsequent recovery in the hospital wards.

Effects of the Injection of the Protective Serum.

Clinical experience varied on this point. At some hospitals nearly every patient had severe serum sickness, perhaps with its own rash and vomiting, and certainly with severe joint and muscle pains. Other observers never saw such effects. The differences were not explained by reference to any particular batch of serum, or to different effect of calf or of horse serum respectively. There were, however, no examples of dangerous anaphylactic phenomena.

It was difficult to form a clear conclusion as to the benefit of the serum. Some observers thought they had proof of its power to control albuminuria and focal reactions in the lungs, if given early and before these features became serious; others were not convinced.

In general, serum was freely used for severe cases of infection. A few trials were made of the influence of the serum on the general state of a tuberculous patient apart from the use of sanocrysin, but they led to no demonstrable results.

Summary of Clinical Results.

Clinical experience in Britain has confirmed the description in Professor Moellgaard's book, of the immediate effects of sanocrysin, as seen in Danish hospitals. The drug does appear clinically to have a specific action on tissues infected by tubercle bacilli, and the severity of the constitutional reactions does appear to be directly related to the intensity of the tuberculous infection. Further, the drug seems to have but slight toxicity for human patients who are infected by tuberculosis, though in this respect very few control observations have been made. On account of the severity of the reactions in the first tuberculous patients chosen for treatment, no observer at the beginning felt justified in deliberately making control observations in other febrile infections. For the same reason no one cared to begin straight away with the treatment on a large number of tuberculous cases, but each observer preferred to select three or four individual patients and proceed cautiously.

The total number of cases covered by this preliminary report is small—about thirty, of whom twenty-two definitely had tuberculous infections of the lungs. Two of the pulmonary cases died, death in one hopeless case being perhaps accelerated by the treatment, and occurring in the other unexpectedly as the result of toxic jaundice. The remaining twenty do not lend themselves to any numerical analysis. Uncomplicated pulmonary tuberculosis is a disease of which few physicians can confidently foretell the progress, upward or downward, during any given period of two or three months, which was all the time available for these preliminary observations. But it was the opinion of those observers who had had most experience in dealing with consumption that the early cases of open tuberculous infection of the lungs did show some evident improvement, though there was no dramatic benefit, such as that seen with insulin or salvarsan in their corresponding diseases. On the other hand, cases with more advanced disease did not stand the treatment well, and the condition of some of these has been made worse. The latter experience accords with that of Dr. Secker of Copenhagen. Serious cases of long standing cannot endure the treatment in its present form.

There were two cases, not included in the preceding twenty, in which most striking improvement followed at once upon the use of the drug, both the patients having lain three months in hospital previously without making any advance. One appeared to be a case of closed tuberculosis of the lung, spreading out from hilum glands, though it could not be proved that the pulmonary inflammation was caused by tubercle bacilli and not by some other smouldering infection. The other was a case of tuberculous peritonitis with an encysted collection of fluid that vanished at once upon treatment. In each instance the patient showed the rash and rise of temperature that in other proved cases of tuberculosis have followed the injection of sanocrysin. No case of pleural effusion was treated in this preliminary group because the results in this condition would not have offered any decisive evidence. Lupus of the skin, spinal caries, renal tuberculosis, and tuberculous glands are now being treated, but their progress is not sufficiently advanced to be included in this report.

The evidence, therefore, despite the relatively poor results in open pulmonary tuberculosis—and that is unhappily the commonest form of tuberculosis—is sufficiently encouraging to demand further clinical study. This is particularly so in view of the one experience common to all observers—namely, that the drug seems to exert a specific action on tuberculous tissues. The Medical Research Council expects that many months will pass after the issue of this preliminary report before

any further definite conclusions can be drawn. Trial on a larger scale is now justified, and it is hoped to widen the field of work with the help of more observers. But the Council is of opinion that such further trial and extended observations are imperatively required before it can be clearly stated that this gold salt is of value in the treatment of tuberculosis and before it should be made available for general use in medical practice in Great Britain."

Reviews.

MEDICAL EDUCATION.—By Abraham Flexner. New York: The Macmillan Co., 1925. Pp. 334. Price, \$2.50.

THIS volume is a valuable contribution to the study of medical education. It deals with the subject from a comparative point of view and gives a graphic view of the conditions which exist in America, Great Britain and the chief European countries.

Abraham Flexner has already issued a valuable work on medical examinations in Bulletin No. IV of the Carnegie Foundation. An adequate review of the book would form a small treatise on the whole subject of medical education and for this reason it is only possible to deal briefly with some of the chief features of the work and to urge on all who are concerned with medical education to obtain and study the volume for themselves. The first chapter deals with the aims and methods of medical education and points out that these are essentially the same as ever in that they consist in observation, description, inference and verification. The use of modern equipment has given rise to difference in details rather than to new principles. The practitioner employs the same mental processes as the investigator and his training should be of such a kind that he will be capable of bringing an acute and informed intelligence to bear on the problems which confront him in practice.

Medical schools are classed in three groups:—

(1) The clinical which is seen in France and England; this has grown out of the hospital, and the scientific subjects have been appendages of the hospital rather than distinct and autonomous units. In England the scientific subjects are now being emancipated from the control of the hospitals and are being taught more and more by experts rather than by young physicians and surgeons.

(2) The University type of medical school, which was developed in Germany and other northern European countries, has teachers who are engaged in research work as well as in teaching, so that a higher degree of specialization obtains in the staff. The pre-war laboratory equipment of the university schools was ample in Germany and other countries while it remained meagre and poor in England and France. The result was that in Germany the medical student learned from scientists while in England and France he learned from physicians and surgeons.

(3) The third type which used to prevail in America consisted of loose agglomerations of practising physicians who imparted, chiefly by lectures, the empirical knowledge which they possessed. It is quite evident that the American medical education of twenty years ago deserved the low esteem in which it was held.

It must be clearly understood that such a state of affairs no longer exists and that the better students have opportunities of learning their profession which cannot be excelled in any part of the world.

In America and in England the clannish spirit appears to be too prevalent, teachers have little chance of obtaining employment outside of their own medical schools, whereas in Germany a career is open to men of distinction in any of the universities of the German-

speaking countries. Curiously enough it is in the smaller provincial medical schools that distinguished young teachers from other schools have their best opportunities, and for this reason the teaching at these schools is less parochial than in the more famous schools. The pros and cons of whole time clinical appointments are very fairly discussed, and on the whole the verdict appears to be given to the whole time units as being more likely to lead to scientific advances than the system of employing busy practitioners. Probably the ideal will be a combination of the two systems, for the whole time teacher has little experience of the lines of practice which lie outside of the hospitals.

The preliminary education of the medical student is fully discussed, and it is evident that Flexner considers that the students of the continent of Europe have a more definite scholarly general education than the students of England and America.

In England there is a group of students whose preliminary education is of a high standard, but the average medical student has a mediocre intellectual equipment, and so there is a great variation in the quality of the students. In America, on the other hand, all the students, whether they be brilliant or mediocre, go through exactly the same preliminary training and many of them are allowed to enter on the medical curriculum with a poor education.

In the medical course the American student almost invariably passes out after four years whether he be good or bad; during these four years he may have had nearly five thousand hours of instruction, and so there is but little opportunity for the exercise of initiative in the selection of his line of study. An attempt is now being made in some of the schools to break away from this mechanical curriculum. The course of study is far too extensive and far too complete to allow of any academic freedom.

In Germany the student has an almost unlimited power of selecting his subjects and his teachers; all that is insisted on is that he should satisfy his examiners that he has acquired the requisite amount of knowledge. In England there is a six years' course of study of which, however, one year is given up to chemistry, physics and zoology, so that the curriculum is one year longer than in America, but there is more weeding out, so that less than half of the students complete the course in the minimum time. The control is less rigid and so opportunities are given to students to pay special attention to the subjects in which they desire to specialise. There was a feature of some of the German examinations which would appeal to many of the weaker brethren in other countries "a student who fails is re-examined in six weeks, if he fails again he is re-examined and practically no one is allowed to fail a third time." This feature is now being abolished, the student who fails the second time is not allowed to go up again.

An interesting account is given of the varied methods of instruction which are adopted in the different countries and schools, but the conclusion is reached and the responsibility should be laid on the student himself, not on the teacher. This is a most important point which needs to be stressed in the Indian medical colleges, as Flexner rightly says "the student who needs to be controlled from day to day, has mistaken his calling". It is interesting to note that the practical work in physiology, etc., which is so extensively adopted in the British schools is greatly neglected in Germany and France.

It is curious to read that in France a student may graduate without ever having seen a post-mortem done. Flexner summarises his views on the improvement of American medical education by insisting that the schools should adopt the university freedom which exists on the continent of Europe and the selection and fostering of the most able students which is a feature of the English schools. The clinical teaching in

Britain is regarded as the soundest, there is a preliminary course in physical diagnosis, then the student takes up a clinical post under the eye of the qualified staff: in fact he learns the work of the doctor by doing what the doctor has to do and by being shown his mistakes. Lectures take a subordinate place, and there is great laxity in the attendance on these unless the students find them instructive and entertaining. The defect of the system of clinical teaching is that it is too practical and lacks the scientific spirit which is so prominent in the British teaching of physiology.

In France it is only the favoured few who ever get an opportunity of going through the apprenticeship which is so valuable a feature of the British system. The French system is also defective in that the student is plunged into the technicalities of clinical work before he knows anything of anatomy and physiology.

The German system consists chiefly of admirable demonstrations; it differs from the British system in that the apprenticeship method is not adopted. The student has plenty of opportunities of watching the masters at work, but they seldom get a chance of doing things for themselves. In America the training tends to be didactic and spoon feeding is the rule, but practical training is obtained by the majority of the young graduates by taking an internship in a hospital after graduation. Curiously enough the chief criticism of the American system is that it is over organised, over co-ordinated and over administered.

The influence of examinations on the student's work is rightly emphasised. The combination of oral, written and practical examinations is regarded as forming the best test. The examination of the Con-joint Board in England is regarded as being excessively practical but we are inclined to think that it is hardly possible for final medical examination to err in the direction of being too practical.

There is a thoughtful chapter on institutes for medical research and their relationship to medical education. "The institute for medical research is not to be regarded as something fundamentally different from the university faculty of medicine; it is a partial faculty, a co-operative group of workers devoted to training as well as to investigation."

The chapter on the costs of medical education is of great interest; fifteen years ago the German universities were far better equipped than any others, the salaries of the professors were paid by the State and the fees of students went to swell the total income of the teachers; at that period the expenditure in England and America was much less, it came almost entirely from the fees of students and the laboratories were poorly equipped for the most part. At the present time Germany is much worse off, France is not so well provided for as it was, in England some head-way has been made, thanks to the fact that Government has provided a certain amount of financial aid, but it is noted that far greater sums will be needed to provide modern facilities and to maintain a competent scientific personnel.

America is in the fortunate position of having vastly greater resources at her disposal than she had fifteen years ago, the funds coming partly from State sources, but largely from private benefactors.

Part of the increased budget has gone to provide better buildings, better equipment and a larger staff of teachers, but there is a tendency to over organise and to spend too much on administrative expenses. At the same time the number of students under training has been rigidly restricted, so that the cost of training each medical student is far in excess of what it was a few years ago.

Flexner has not produced a universal panacea for the ills of medical education; each country and each medical school has its own problems which cannot be solved by any cut and dried scheme; but all who are interested in medical education must read Flexner's book, it constitutes the only existing scientific study

of the subject. It is written in an easy and interesting manner; and invariably we find that both sides of the question are stated.

MANSON'S TROPICAL DISEASES.—Edited by Philip H. Manson-Bahr, D.S.O., M.A., M.D., D.T.M. & H. (Cantab.), F.R.C.P. (Lond.). Eighth Edition, Revised. Demy 8vo, about 916 pages, with 6 maps, 20 colour plates, 7 halftone plates, 387 figures in the text and 33 charts. London: Cassell & Co., 1925. Price, 31s. 6d. net.

THE appearance of a new edition of Manson's "Tropical Diseases" is always an event of great interest to medical men in the tropics. This eighth edition in one sense forms the coming of age of the book as it is the twenty-first time that it has been reprinted since it was first published in 1898.

For some years Manson's book was the only satisfactory guide to the student of tropical diseases and it has probably been the chief influence in stimulating the study of exotic medicine by English-reading medical men. It is a matter of great regret that the master-mind of its original author has been removed by death since the appearance of the last edition in 1921.

The chief features of this edition are:—

(1) It has been brought thoroughly up to date by Dr. Manson-Bahr who has long been associated with the editing of the book.

(2) Six new maps have been prepared; these show clearly the distribution of some of the more important tropical diseases.

(3) The section on medical zoology has been entirely re-written.

(4) The work has been remodelled to bring it abreast of recent developments in tropical medicine.

(5) Ninety-four new illustrations have been supplied.

(6) The book has been kept within reasonable compass, being shorter than the previous edition by about 70 pages.

These points suffice to show that every effort has been made to adapt Manson's great work to modern requirements and it is certain that its popularity will be well maintained.

In reviewing the former edition a few errors of importance were pointed out, these have been removed in part but it is necessary to protest again that the seven-day fever of Japan is quite distinct from Roger's seven-day form of dengue and that epidemic dropsy is not the same disease as war oedema or famine dropsy.

It is natural that there should be sharp differences of opinion regarding many debated points in tropical medicine and no useful purpose would be served by entering into a discussion of these in a review like this, but if there are reasons for adopting views widely divergent from those of other workers on tropical medicine these should be stated by the author.

In discussing the treatment of liver abscess it is stated that "the surgeon must be prepared to drain the abscess if pus be discovered; once diagnosis is established nothing is gained by delay" but later on we find that the editor himself has successfully treated 15 cases by aspiration alone combined with emetine treatment. Presumably the former statement has been allowed to stand by an oversight, but it certainly conveys a wrong impression of the accepted modern treatment of liver abscess.

We also think that it would be wiser in the case of a patient who is in the "pre-black-water-state" or who has previously suffered from the disease to desensitize him by giving minute and gradually increasing doses of quinine rather than to give doses of 5 grains of quinine straight away.

In the chapter on kala-azar the description of the aldehyde test (or formal-gel reaction, as the editor persists in calling it) is misleading.

As his experience is limited to six "well-marked" cases of kala-azar his expression of the opinion that the test is untrustworthy need not be taken very

seriously but we must quarrel with his statement that "Napier himself states that 'jellification' may be taken as absolutely diagnostic of kala-azar". Napier has certainly never made such a statement; he has always insisted that opacity rather than jellification is the change on which the diagnosis of kala-azar is dependent, that jellification alone is frequently observed in other conditions but that jellification plus complete opacity is the only change that is absolutely diagnostic of kala-azar.

To pick out flaws and to indicate differences of opinion is easy, but to do so on a large scale would create an entirely wrong impression of the book: it forms a clear and masterly exposition of sound modern teaching in tropical medicine and will doubtless continue to be the most popular text-book on the subject. There are nearly 400 excellent illustrations and 27 beautiful plates, the general "get up" of the book is of the highest standard and the price moderate when everything is considered. We congratulate the author and the publishers on their achievement in producing so worthy a successor to the previous editions of Manson's "Tropical Diseases".

MEDICAL OPHTHALMOLOGY.—By R. F. Moore, O.B.E., M.A., B.Ch. (Cantab.), F.R.C.S. Second Edition. London: J. & A. Churchill, 1925. Pp. 344, with 8 plates and 92 illustrations. Price, 18s. net.

The first edition of this book has been a great success and regarded as the best book on the subject in the English language, and this new edition is a great improvement on the earlier one.

The whole book has been revised, and made fuller and more systematic and is now a very complete résumé of a branch of ophthalmology which is becoming of more importance day by day, as the relationships between morbid conditions in the eye and diseases of other parts of the body are worked out; and in many diseases, especially those of metabolism, and of the nervous system, the ophthalmologist can give material help in a difficult diagnosis to the physician.

The indexing and arrangement of the book is excellent, rendering reference to any point easy, and the addition of 8 new coloured plates and a number of black and white illustrations, all well done and useful, adds greatly to the merits of the book.

It should be in every ophthalmic library, and should be studied by every physician who wishes to be up-to-date in modern methods of diagnosis.

AN INTRODUCTION TO SURGICAL UROLOGY.—By William Knox Irwin, M.D. (Aberd.), F.R.C.S. (Edin.). London: Baillière, Tindall & Cox, 1923. Pp. viii plus 180. Price, 7s. 6d. net.

The author claims for this book that it gives 'the main facts of the subject in short compass'.

The anatomy of the part concerned and the examination of the patient occupy the first two chapters. The subsequent chapters deal with the prominent symptoms of urinary diseases, their ætiology and treatment. The last chapter describes the pathological changes occurring in the prostate in later life.

The book is necessarily limited in its scope, but will prove valuable to students about to begin the study of genito-urinary diseases, and also to practitioners who require a small book of ready reference.

MEDICAL AND SURGICAL REPORT OF THE ROOSEVELT HOSPITAL, NEW YORK. (Second Series) 1925, based on the work of the years 1915—1924 inclusive. Paul B. Hoeber, Inc.: New York. Pp. 378. Price, \$5.00 net.

This excellent volume compiles the second series of 34 articles and written by 22 members of the Hospital Visiting Staff.

It contains both medical and surgical articles and is full of interest. The varied subjects are discussed in a concise, clear way and form delightful reading. The

articles are essentially practical and contain a large quantity of scientific information. The illustrations are numerous and deserve a special word of praise and add greatly to the value of the book.

A summary completes the ending of most of the articles. The two articles on partial colectomy are especially good and the technique employed is made easy to follow by the many illustrations.

Other excellent articles are the two on breast tumours and the surgical treatment of chronic duodenal and gastric ulcer. The author is to be congratulated on the successful treatment of a case of cerebellar abscess.

We cannot agree with the author in his methods in the treatment of fracture of the femoral shaft in adults. The apparatus devised by Hamilton Russell of Australia in which no splint is used and largely employed in this country, has proved eminently satisfactory and renders skeletal traction far less common.

The book will be found most useful to the surgeon and physician and we thoroughly recommend it as likely to find a useful place in their library.

AN INTRODUCTION TO THE MIND IN HEALTH AND DISEASE.—By T. Waddelow Smith, F.R.C.S. (Eng.). London: Baillière, Tindall & Cox, 1925. Pp. viii plus 236, with 6 coloured plates. Price, 10s. 6d. net.

This work is intended as an introduction to the study of mentation, a stimulus to students entering upon this subject and an aid to general practitioners in dealing with cases of psychic origin.

The author in his preface stultifies himself at once by admitting, what is at once obvious to anyone with any knowledge of this subject, that many controversial and hypothetical points have been dealt with in the text as facts. This at once destroys the value of such a work and nullifies the attainment of its stated purpose. Students and tyros cannot be too accurately instructed and to give them as facts only one side of a question on which controversy is acute is wholly wrong and undesirable.

The book too seems badly balanced, some aspects of the subject being dealt with in too elementary and cursory a manner while other aspects are infinitely more scientifically dealt with.

The sections dealing with psycho-analysis are interesting as they unwittingly lay bare most of the defects and fallacies of the Freudian school. The author's remarks, that no one should dare to practice it before, if he be a man, the age of fifty, if a woman, that of forty, because the emotional tone is so strong in the healthy minded before that age that there is a great likelihood that it would drive everything before it and compel the analyst to close his work, give one food for thought. How about the climacteric period in woman, is it not an admitted fact that the emotional tone in woman is markedly unbalanced at this critical period of life?

The above is but one of several similar statements that have been noted and speaks for itself.

On the whole, therefore, the book is one which does not seem to us to appeal to any class of reader.

A CLINICAL HANDBOOK OF MENTAL DISEASES.—By Lieutenant-Colonel W. S. J. Shaw, I.M.S. Calcutta: Butterworth & Co. (India), Ltd., 1925. Pp. 235, with 2 charts. Price, Rs. 3-8 net.

COLONEL SHAW has given us a book on mental diseases which will appeal to all medical students and practitioners throughout India. The book is no more than it pretends to be, i.e., a handbook. There is no superfluous material in it and it covers every aspect of psychiatry which is at all likely to be of use to anyone in the practice of medicine. It will prove a ready reference to the busy general practitioner when procedure as to the proper disposal of mental cases is in question. At this time when the teaching of psychiatry in the medical schools of India is in the hands of teachers, who, with few exceptions, know little of their

subjects, it is opportune that a handbook of this nature should be available to all medical men in India to whom psychiatry has been and is a neglected subject.

Colonel Shaw has had many years' experience in India in the practice of psychiatry. Unlike most authorities in this subject who strive to be original, this handbook expresses no dogma, is very readable, technical terms are explained in a simple manner and no attempt is made to coin words or overwhelm the uninitiated mind with high-sounding terms so dear to the psycho-analytical school. The classification adopted is that of the official "Nomenclature of Diseases." The legal aspect of psychiatry is adequately dealt with as regards procedure in so far as it may affect the general practitioner. There is also a chapter on the lay-out and construction of a mental hospital in India with two sketch plans which are self-explanatory. This chapter contains many useful hints in mental hospital construction in India. A chapter is also devoted to procedure in regard to military insanes as well as to the transmission of insanes to England and elsewhere.

In a book of this nature it is impossible to deal adequately with the subject in hand, but sufficient is explained in order to give the student a bird's-eye view of what he is looking for. On the whole the chief defect of the book is its brevity but it has succeeded in what, to my mind, are the two chief drawbacks in books on this subject, namely, the tendency to use a prolixity of words and abstruse phrases and to fill in the context with histories of cases which are too much of the smoke-room type for a sober text-book on psychiatry.

One minor point of criticism suggests itself—the general construction of the book. It is unprepossessing in appearance and in not a few instances someone has blundered in the spelling of words.

IMMUNITY IN NATURAL INFECTIOUS DISEASE.—

By F. d'Herelle. English Edition by G. H. Smith, Ph.D. Baltimore: William & Wilkins Co., 1924. Pp. 400. Price, \$5.00.

It is impossible in a short review adequately to describe an important work of this kind which is on highly original lines. In it the author's views on many problems of immunity are set forth, views which are strikingly different from those held by many leading workers. One cannot fail to be struck by the freshness of Dr. d'Herelle's treatment of many familiar subjects, but whether his views will prevail remains to be seen. With regard to the bacteriophage there is of course nothing *a priori* improbable in the idea of the existence of forms of life which may attack bacteria. Ideas on the subject of bacteria are apt to be anthropocentric. He makes a good deal of the point that laboratory studies on immunity have largely been carried out on refractory animals, and are therefore divorced from the evolution of natural immunity in the susceptible. The mechanism of natural immunity is no doubt different in different cases. In some cases it would appear to be really acquired immunity. In other instances its origin is obscure.

The book is powerful and stimulating and it will take its place among standard literature on immunology.

The translator has rendered the book into clear and forceful English.

FORENSIC MEDICINE.—By Harvey Littlejohn, M.A., M.B., B.Sc. London: J. & A. Churchill. Pp. 285, with 183 illustrations. Price, 15s. net.

PROFESSOR HARVEY LITTLEJOHN has made an important contribution to medico-legal literature by publishing an atlas of selected medico-legal subjects from specimens in his collection.

The chief feature of the book is the numerous splendid illustrations. Short descriptions of these and introductions to the various subjects are also given. Illustrations in medico-legal works are frequently unconvincing, and the photographs in this work are better than anything we have previously seen. Among

the subjects considered are post-mortem conditions, drowning, hanging and strangulation, the effects of fire-arms, burns, cut throat, wounds, fractures, etc. Especially interesting is the account of gunshot wounds. The book concludes with some excellent photographs of the hymen, illustrating various types. The author points out that the opinions of medical men as to the presence or absence of rupture of the hymen are frequently erroneous owing to insufficient knowledge of the various types of hymen in the virgin.

Being from the pen of Professor Littlejohn, this work is, of course, authoritative, and it will take its place among the leading medico-legal works of our time. The book is an excellent one and should be in every medical library.

A TEXT-BOOK OF PATHOLOGY.—By J. Martin Beattie and W. E. Carnegie Dickson. Third Edition. London: William Heinemann (Medical Books), Ltd., 1925. Pp. 1103, with 499 illustrations in the text and 17 coloured plates. Price, 42s. net.

A DETAILED description of this well-known book which is now in its third edition would be superfluous. The popularity of the first edition is demonstrated by the fact that it was necessary to reprint it five times.

Much new matter has been added since the last edition but this has not been done at the expense of the material contained in the last edition.

In the first half of the book the nature of the pathological changes that occur in the body are well described. The hundred pages on the subject of animal parasites, protozoa, helminths and arthropods, will be of particular interest to readers in this country. The life history of the malarial parasite is well demonstrated by diagrams and there is a very good coloured plate of the forms that are encountered in the peripheral blood. The most recent work on the amœbæ and the intestinal flagellates has obviously been carefully consulted before the chapter on protozoa was written.

In the second half of the book each system or organ is dealt with in a separate chapter. The pathological changes that occur in the blood are well shown in a number of very beautiful coloured plates. The subject of ductless glands has been dealt with sufficiently fully and this chapter has been brought up to date, but the authors have not allowed themselves to be unduly influenced by the present boom.

The book is well written, well illustrated (by nearly 500 clear text figures and 17 coloured plates) and well printed. The student or practitioner will experience great difficulty in finding a better book on pathology.

INTERNAL SECRETION IN HEALTH AND DISEASE.

—By Captain Y. M. Bose, M.D. Calcutta: Butterworth & Co. (India), Ltd., 1925. Pp. 550, with 43 illustrations. Price, Rs. 12 net.

DURING the last decade the literature published on the internal secretion and ductless glands has been so vast that it has been difficult for an ordinary practitioner to follow it. A number of handbooks have been written to keep him in touch with modern advances in endocrinology and Dr. Bose's book is one of this type. It reviews fairly fully all the latest work on the internal secretion and gives the accepted views in a clear and concise form leaving out all controversial details. The subject matter is well arranged and we have no doubt that the book will be useful to both the student and practitioner.

BULLETIN NO. XI OF THE INTERNATIONAL ASSOCIATION OF MEDICAL MUSEUMS AND JOURNAL OF TECHNICAL METHODS. New York: Paul B. Hoeber, 1925. Pp. 151. Price, \$3.00 net.

THE eleventh of these valuable bulletins appeared on May 4th, 1925.

The editorials are interesting and especially that dealing with pathological service.

It stresses what should be obvious to all teachers in medical schools:—the value of autopsies to the medical service in the hospital.

The handicap to a hospital, and especially to one in which medical students are being taught, of restriction of the number of post-mortem examinations carried out, is very great indeed.

Original communications are of interest and there are, as well, many short descriptions of simplified methods of technique applicable in the museum and the laboratory.

These bulletins, and, in fact, membership in the Association, are of a great deal of value to hospital and medical college pathologists.

A TREATISE ON MATERIA MEDICA AND THERAPEUTICS.—By the late Rakhaldas Ghosh. Tenth Edition by B. N. Ghosh, F.R.F.P. & S. (Glas.). Calcutta: Hilton & Co., 1925. Pp. 718. Price, Rs. 7-8.

THE fact that this book has gone through ten editions since 1901 is sufficient proof of its popularity. The present edition has been brought up-to-date and many recently introduced drugs, such as new compounds of antimony and bismuth, carbon tetrachloride, insulin, etc., have been included. We strongly recommend this edition to students and practitioners.

Annual Reports.

ANNUAL REPORT OF THE BURMA GOVERNMENT MEDICAL SCHOOL, RANGOON, FOR THE YEAR 1923-24. BY LIEUT-COLONEL A. WHITMORE, M.D., I.M.S. RANGOON: SUPERINTENDENT, GOVERNMENT PRINTING, BURMA, 1924. PRICE 4 ANNAS.

THE year commenced with 175 students on the roll, and, though the school is still a small one, its numbers are steadily growing, 32 new students being admitted during the year, all of whom had passed either the High School Final or the Matriculation examination. Twenty-two students passed out during the year, and there were 10 casualties. Forty-five third year students were sent to Madras to undergo training in practical midwifery at the Government Maternity Hospital there, as there is no local provision in Rangoon. It is hoped however that facilities will be provided at the Dufferin Hospital, Rangoon.

There were numerous changes of staff during the year, owing to the transfer of officers,—a matter which seriously affects the teaching in all medical schools in India. Receipts during the year amounted to Rs. 5,130 and expenditure to Rs. 1,00,908. The annual prize distribution was held on December 20th, 1923 when His Excellency Sir Harcourt Butler was present. The sports at the schools are still hampered by the want of a playing field in the vicinity of the school, but the students carried off the Junior League Challenge Cup and were runners up in the Junior League Football competition. The School Union also took a very active part in the Health Week Exhibition.

PROCEEDINGS OF THE ASSAM BRANCH, BRITISH MEDICAL ASSOCIATION ANNUAL MEETING, JORHAT, 2ND MARCH 1925. CALCUTTA: THE LYONS PRESS.

THE Annual Meeting of the Assam Branch of the British Medical Association took place at Jorhat on March the 2nd. Dr. E. T. Jameson in his presidential address reminded the Meeting that at the termination of their last Annual General Meeting there were several matters left in the hands of the Committee to carry through. These included, (1) the proposal for the manu-

facture of Vaccines for Pncumonia, and that this matter should be put before the Government of Assam with a view to the work being undertaken by the Pasteur Institute in Shillong; (2) to reply to certain correspondence with the Dominions Committee with reference to the subject which was before the Meeting under the name of "Care of Labour;" (3) to approach a recognized Medical Transfer Agent with regard to assisting,—with advice to intending applicants for appointments in Assam.

Certain difficulties have arisen with regard to the preparation of vaccine at the Pasteur Institute, Shillong. The Calcutta School of Tropical Medicine has been approached on this subject; although expressing their willingness to help in the matter, they have pointed out that the manufacture of vaccine on a large scale is a matter of funds. The matter is now in the hands of the Indian Tea Association. A reply was sent to the Dominions Committee and, with regard to the question of medical officers, the Secretary of the Indian Tea Association has suggested that grievances of newly arrived medical officers be referred to the Council of the Association.

Conditions for the medical man in the province have improved very considerably during the last few years, roads are better and he is supplied with better equipment, so it is to be hoped that more research work will be done and some of the many problems that are outstanding—such as Naga Sore,—may be solved.

Dr. G. C. Ramsay gave a few impressions on some diseases of Assam. One of the most important diseases in the tea gardens in Assam is pneumonia which in some gardens has accounted for 30 to 40 per cent. of the total deaths. One of the main causes is the habit of sleeping on the damp ground, (or on the roadside after a drinking bout) and it seems possible that if the coolie could be induced to sleep regularly on a machan this cause of death would be reduced.

Tertiary lesions of syphilis appear to be much rarer in malarious districts and parasyphilitic lesions are almost unknown.

Bacillary dysentery represents 95 per cent. of the dysenteries in Cachar and it seems worth the while of the Government of Assam considering the advisability of manufacturing serum in this country instead of depending on the products from America and England which have undergone deterioration in transit.

There are many other medical problems which are awaiting solution in this province, as for example Naga Sore and epidemic conjunctivitis. It seems a pity that the Government of Assam should curtail the activities of the Pasteur Institute at Shillong, the only institution in the province in which research work can be carried out.

Lieutenant-Colonel F. J. Palmer, R.A.M.C. (retd.) read a paper on the treatment of leprosy by metallic salts. He advocated the giving of copper sulphate gr. $\frac{1}{2}$ daily for three weeks; the treatment should then be suspended for a week and the salt again administered.

He quoted a few cases in which improvement had occurred.

He concluded:—

(1) That in copper and bismuth salts we possess two of the most powerful agents yet introduced for the treatment of leprosy.

(2) They are very inexpensive, at least at present.

(3) They both, earlier or later according to frequency and dosage, produce focal reactions in leprotic tissues.

(4) That this reaction would appear to be curative, and that even advanced cases have so improved as to justify the hope that final cure is not far off.

(5) That with increasing knowledge speeding up may be possible.

(6) That cure can only take place through a series of reactions, and that these may be severe in advanced cases, and for a time make the patient appear worse.

(7) That the potentialities of oral administration of copper, and with less certainty, those of intramuscular bismuth are worthy of trial.

On a few occasions during the past year, when unexpected ulcers began to appear in apparently new places, and when the patient's condition appeared to be worse, I have faltered by the way, and my courage has well nigh failed me. Now, with increasing confidence, I believe we can look forward to the end, and, when further experience in the use of these, and perhaps other compounds, has been gained, to the permanent cure of leprosy in the great majority of the sufferers whom it now afflicts. In advanced cases, however, it will not be easy, and courage and perseverance will be required from patient and physician, and a good deal of faith from both.

Lieutenant-Colonel S. R. Christophers, I.M.S., read a paper by the members of the Kala-azar Commission on the kala-azar transmission problem.

Rogers' discovery of the flagellate stage of the parasite first pointed to the possibility of insect transmission, but it must be borne in mind that some other means of transmission may occur. There is a still further possibility that man may be only a cul-de-sac and that the infection may be transmitted from a plant, an insect or any other vertebrate. Evidence goes to show that transmission occurs from man to man but this is as yet not proven. Infection may take place from man to man directly, as in contagious disease, indirectly, as in cholera, typhoid, etc., or by means of an intermediate host. Experimental work has so far not supported the first theory. The second theory is supported by many laboratory observations and has a certain amount of epidemiological support; we are carrying out work to test this theory at present. This brings us to the third theory which is the most probable one. The intermediate host might be an intestinal worm, such as anchylostoma, or it might be a blood-sucking insect. The possibility that Anchylostoma is the intermediate host has been to a certain extent negated by many observers. Up to the end of last year little progress had been made with any insect; the bed-bug was tried because under artificial conditions development of the parasite of the disease occasionally took place in its gut. The first real advance was made when Knowles, Napier and Smith of the Calcutta School of Tropical Medicine demonstrated that flagellates could be found in the gut of laboratory-bred *P. argentipes* after the sandfly had been fed on the blood of a kala-azar patient. The results of these workers have been confirmed by the Commission working in Assam. There appears to be no doubt that not only flagellation, but rapid and characteristic multiplication of forms takes place. Proof that the sandfly is the transmitter of the disease is, of course, still wanting but it must now be considered the principal suspect. Another group of insects on which epidemiological observation has thrown suspicion is the culicoides; many varieties have been found in Assam but so far no support has been gained from laboratory experiences.

Dr. F. W. O'Connor in a very short paper made a plea for the more extensive use of the electric sigmoidoscope in tea garden practice. By means of this instrument it was possible to see the conditions which could otherwise only be guessed at even if repeated microscopic examination of the stools were made.

Dr. C. Strickland read a paper on the mosquito factor in the malaria of Assam and its prevention. This paper will appear *in extenso* in an early number of the *Gazette*.

CENTRAL PROVINCES AND BERAR, ANNUAL PUBLIC HEALTH REPORT FOR THE YEAR 1923. BY LIEUTENANT-COLONEL T. G. N. STOKES, M.B., I.M.S. NAGPUR: SUPERINTENDENT, GOVERNMENT PRINTING, C. P. 1924. PRICE, RE. 1.

THE monsoon began somewhat late, but the total rainfall was normal except in the west of the Central Provinces where it exceeded the average by 20 per cent. The climatic conditions of the year were generally favourable to public health; crops were good, prices of food-grain lower than in the year 1922, water was

plentiful and there was no epidemic disease except mild outbreaks of plague and cholera in a few districts.

The birth-rate of the year is the highest during the past five years, the number of births registered being 45.63 per 1,000 of the population against 35.80 in the previous year and 38.08 in the last quinquennium. Deaths numbered 30.53 per mille as against 29.31 in the preceding year and 51.85, the quinquennial figure. The mortality amongst children is always far in excess of that amongst adults, and with a high birth-rate, an increase in the death-rate is a normal feature; it is therefore satisfactory to find that, notwithstanding the high birth-rate of the year, the death-rate is little in excess of that of the previous year which was the lowest recorded for 20 years.

Children under five years of age were responsible for a little more than half the total mortality. Of these children one-third (32.9) were infants, of whom 10 per cent. (9.8) died in the first week, from natal or prenatal causes. The problem of infant mortality is receiving considerable attention and it is satisfactory to note that many municipal committees are beginning to realize their responsibilities in this matter and have provided for the visiting of mothers and infants by a municipal midwife or female sub-assistant surgeon. The Maternity and Child Welfare League in Nagpur, the management of which was taken over by the Municipal Committee, has obtained some striking results. The large decrease in the death-rate among infants under one month in the area under its charge proves that many deaths among infants are preventable if the problem of infant mortality is approached scientifically. During the period under review Nagpur city organised a Health Week and a Baby Show in October and November. Amraoti also celebrated a Health Week in December. On the initiative of Her Excellency the Countess of Reading a National Baby Week was celebrated during the third week of January 1924. These celebrations evoked an encouraging response and aroused great interest in many places. They have undoubtedly a great educative value and have stimulated among considerable sections of the public a realization of the importance of national health both to individuals and to the country generally.

The Director of Public Health reports that the Publicity Officers and also the officers in charge of travelling dispensaries have performed a large amount of useful propaganda during the year, especially in connection with Baby Week. He urges that the former should be made permanent and the number of travelling dispensaries increased. The Local Government agreed that steps should be taken to strengthen the publicity section of the Public Health Department at an early date, but unfortunately the attitude of the Legislative Council in refusing all grants prevented the Local Government from providing the sums necessary for this purpose. Any considerable extension of the activities of the Public Health Department in the direction of publicity must be dependent on the voting of funds by the Council. Much can be effected by District Councils and Municipalities in the problem of infant mortality and in general publicity work.

As usual, fever was responsible for the great majority of deaths. Out of the death-rate of 30.53 per mille, 16.79 per mille are attributed to fever, while plague caused 15,867 deaths, the ratio of the latter being 1.14 per mille of the population. The Director is of opinion that if reasonable and timely measures had been taken in Jubbulpore, Akola and Yeotmal, the plague epidemic would have been far less severe. In Nagpur during the last six years a systematic, vigorous and sustained campaign of rat extermination has been pursued, and in that period notwithstanding the fact that the surrounding localities have been badly infected, that from time to time imported cases of plague have occurred, and that amongst the rats trapped a few have been found to be suffering from the disease, there has been no plague epidemic in Nagpur. The immunity of Nagpur has attracted the attention of other municipal committees, and rat extermination campaigns have been undertaken

Oct., 1925.]

in many of the larger towns. It is an established fact that certain towns constitute centres from which plague infection spreads annually over the province, and it is of the utmost importance that anti-plague measures should be undertaken not only in the interests of the residents of such towns but for the safety of the whole province. It is however, regrettable to find that some municipal committees do not realize their responsibilities in this matter. Thus in Jubbulpore, whence annually plague spreads over the north of the province, the municipal committee on the ground of retrenchment has reduced its grant to the hospital, decreased its sanitary staff, refused to provide a salary sufficient to employ a fully qualified health officer, and failed to undertake vigorous measure for the prevention of plague. When it is remembered that the financial difficulties of the municipal committee arise almost entirely from the annual plague visitation, which by the consequent dislocation of trade reduces the income of the municipality, the attitude of the committee is the more to be regretted.

Owing to the financial position in the province Government was not in a position to increase its grants for sanitary schemes. Recurring grants were made amounting to Rs. 36,724, which is approximately equal to the grants given in the previous year. Rs. 10,000 were also granted for the improvement of the water-supply in rural areas in Berar. The financial position has now fortunately improved.

The total income of municipal towns in these provinces in the year 1922-23 exclusive of loans and balances was Rs. 52,01,531 as against Rs. 47,48,357 in the preceding year. Of this amount, Rs. 19,80,277 was spent on public health purposes. This represents 38 per cent. of the total as against 46 per cent. for the year 1921-22 and 50 per cent. for the year 1920-21. This reduction in expenditure on public health is regrettable, but there is some reason to suppose that as a result partly of the publicity work which has recently been undertaken, local bodies are beginning to realise their responsibilities in this matter. Much can be done without additional expenditure, by careful supervision, by the enforcement of sanitary by-laws, and by the personal influence of members of local bodies. The Director's report makes it clear that there is room for improvement even in the larger municipalities.

Correspondence.

INDIAN SCIENCE CONGRESS.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—The Indian Science Congress is to be held in Bombay during January of next year.

As President elect of the Medical Research Section I am writing to ask whether you will be good enough to contribute one or more papers yourself and induce those working with you or under you to do likewise. Papers should be of a length that they do not exceed ten minutes in the reading and they should, if possible, be the results of research or at least have a bearing on some problem of research or be of such a nature as to stimulate discussion on the scientific aspect of some medical problem. This means that purely clinical articles are not suitable.

As I am shortly leaving for England for a short visit, I wish particularly to emphasize the fact that abstracts and preferably the complete paper should be in the hands of Major J. Morrison, I.M.S., Acting Director, Bombay Bacteriological Laboratory, Parel; by October 15th at the latest, otherwise printing of such abstracts and papers may be impossible.

I shall be further obliged if you will kindly signify to Major Morrison as early as possible your intention to contribute a paper and on what subject.

Please also show this to any of your friends who might contribute papers, as it is impossible for me to

know every one in different parts of India who is engaged in Medical Research.—Yours, etc.,

R. ROW, M.D., D.S.C. (Lond.), D.P.H.

BOMBAY BACTERIOLOGICAL LABORATORY,

PAHEL,

18th August 1925.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Lieutenant-Colonel A. Fenton, M.D., I.M.S., Officiating Inspector-General of Civil Hospitals, Burma, is confirmed in that appointment, with effect from the 9th June 1925.

Lieutenant-Colonel J. McPherson, I.M.S., as Agency Surgeon, is posted as Residency Surgeon, Mysore, with effect from the 29th July 1925.

Lieutenant-Colonel H. Innes, M.D., I.M.S., is appointed to officiate as Inspector-General of Civil Hospitals and Prisons, Assam, during the absence on leave of Colonel C. H. Bensley, C.I.E., K.H.P., I.M.S., or until further orders.

The services of the undermentioned officers are placed permanently at the disposal of the Government of Burma, with effect from the dates shown against their names:—

Major S. T. Crump, I.M.S. 1st January 1920.

Lieutenant-Colonel E. T. Harris, D.S.O., M.D., I.M.S. 9th March 1921.

Major H. A. H. Robson, M.B., I.M.S. 13th December 1920.

Major F. Stevenson, I.M.S., an Officiating Agency Surgeon, was posted as Agency Surgeon, Gilgit, with effect from the 1st November 1924.

Major L. H. L. Mackenzie, I.M.S., an Officiating Agency Surgeon, was granted leave on average pay for 8 months combined with leave on half average pay for 1 year and 24 days, under Fundamental Rule 81, with effect from the 1st November 1924.

The services of Major R. E. Flowerdew, M.B., I.M.S., are placed permanently at the disposal of the Government of Burma, with effect from the 28th May 1922, for employment in the Jail Department.

The services of Major R. B. Seymour Sewell, I.M.S., Surgeon Naturalist, Marine Survey of India, are placed at the disposal of the Department of Education, Health, and Lands, for appointment as Director, Zoological Survey of India.

The services of Captains J. B. Vaidya, M. M. Khan, and A. J. D'Souza, M.C., I.M.S., are placed temporarily at the disposal of the Government of Madras, with effect from the dates on which they assume charge of their civil duties.

The services of Captain P. Verdon, I.M.S., are placed permanently at the disposal of the Government of Madras, with effect from the 27th February 1925.

Captain A. C. Craighead, M.B., I.M.S., an officer of the Medical Research Department, is placed on special duty under the Indian Research Fund Association for work in connection with the Kala-azar Commission with effect from the date on which he assumes charge of his duties.

The services of Captain A. H. Harty, I.M.S., are placed temporarily at the disposal of the Government of Bombay for employment as Superintendent, Central Mental Hospital, Yeravda, with effect from the date on which he assumes charge of his duties.

Captain R. Hay, I.M.S., is appointed to officiate as an Agency Surgeon, and is posted as Agency Surgeon in Bundelkhand, with effect from the 3rd July 1925.

The services of Captain S. L. Mitra, I.M.S., are placed temporarily at the disposal of the Government of Bihar and Orissa, with effect from the date on which he takes charge of his civil duties.

The services of Captain E. R. Daboo, M.C., I.M.S., are placed temporarily at the disposal of the Government of Assam, with effect from the date on which he assumes charge of his duties.

LEAVE.

Colonel C. H. Bensley, C.I.E., K.H.P., I.M.S., Inspector-General of Civil Hospitals and Prisons, Assam, is granted 8 months' leave on average pay, with effect from the 1st July 1925.

Lieutenant-Colonel A. Leventon, I.M.S., Superintendent, Campbell Medical School and Hospital, Sealdah, was allowed leave for 2 years, 1 month and 16 days from 11th March 1923 to 26th April 1925, viz., leave on average pay for 6 months and 5 days, under Rule 81 (b) (i), Fundamental Rules, and leave on half average pay for the remaining period under Rule 81 (d) of the said Rules.

Lieutenant-Colonel R. F. Standage, C.I.E., I.M.S., an Agency Surgeon, is granted leave on average pay for 6 months and 4 days combined with leave on half average pay for 26 days, under Fundamental Rule 86, with effect from the 29th July 1925.

PROMOTIONS.

Lieutenant-Colonel (now Colonel) R. W. Knox, D.S.O., M.B., F.R.C.S., I.M.S., to be temporary Colonel from the 23rd November 1918 to 11th November 1919, whilst employed as Assistant Director of Medical Services in Egypt.

Lieutenant-Colonel C. Hudson, C.I.E., D.S.O., I.M.S., to be Bt.-Colonel, with effect from the 1st July 1925.

Majors to be Lieutenant-Colonels.

Harry William Pierpoint, F.R.C.S. Dated the 1st August 1925.

William David Henderson Stevenson, C.I.E., M.D. Dated the 1st August 1925.

Henry Patullo Cook, M.B., F.R.C.S.E. Dated the 1st August 1925.

Percy Strickland Mills, M.B. Dated the 1st August 1925.

William James Fraser, M.B., F.R.C.S.E. Dated the 1st August 1925.

Charles Aubrey Godson, M.C. Dated the 1st August 1925.

Reginald Henry Lee, M.B. Dated the 1st August 1925.

Frank Phillips Warwick, D.S.O., M.B. Dated the 1st August 1925.

William Anderson Mearns, M.D. Dated the 1st August 1925.

Robert George Gibbon Croly, M.B. Dated the 1st August 1925.

Captains to be Majors.

George Henry Mahony, M.B. Dated the 31st July 1925.

Gordon Covell, M.D. Dated the 31st July 1925.

William Ross Stewart, M.B., F.R.C.S.E. (Bt. Major). Dated the 31st July 1925.

Venkatasubba Mahadevan, F.R.C.S.E. Dated the 31st July 1925.

Alured Charles Lowther O'Shee Bilderbeck, M.B. Dated the 31st July 1925.

The promotion to present rank of Major R. Sweet, D.S.O., M.B., I.M.S., is antedated from the 25th January 1925 to 25th July 1924.

Captains to be Majors.

James Findlay, M.B., I.M.S. Dated the 26th July 1925.

William Collins Spackman, M.B., I.M.S. Dated the 26th July 1925.

Manulal Maganlal Mehta, I.M.S. Dated the 26th July 1925.

Charles Henry Powell Allen, I.M.S. Dated the 26th July 1925.

NOTICE.

RADIOGRAPHY IN INDIA.

THE practice of radiography calls both for the services of a specialist and efficient apparatus. The latter is particularly important in India, where the distance from the factory and climate conditions render it imperative that only material of the finest quality be installed.

The specialist is at all times dependent upon the efficiency of his plant and the co-operation of the manufacturer in supplying apparatus that is fully capable of giving consistent results throughout its entire field of application. If the equipment fails to fulfil this object, it at once sets up difficulties for the radiographer and in India where one is more often solely dependent upon the services of a local electrician, these small faults frequently develop into serious troubles and at times terminate in a total break-down.

The qualities inherent in a first-class installation fall mainly under the headings of design, operation and durability.

The design of X-ray equipment, fundamentally, must be based on the soundest electrical and mechanical principles.

From the point of view of the radiographer it is necessary that the layout of the equipment shall have been given careful and expert consideration, and shall be in accordance with the most up-to-date practice. The apparatus itself must combine simplicity with ease of control and at the same time be capable of giving consistent and reliable results.

With the object of giving a really efficient service to radiologists in India, the International General Electric Company, Inc., have now established at their Ballard Estate address, Bombay, a department for the supply of all forms of X-ray and electro-therapeutic apparatus manufactured by the Victor X-ray Corporation, U. S. A. The staff of the X-ray Department of the International General Electric Company, Inc., will be pleased to reply to all enquiries—technical or otherwise—and furnish proposed layouts, quotations and suggestions regarding new plants.

Radiographers throughout India, Burma, and Ceylon, etc., are invited to communicate their address to the International General Electric Company, Inc., when the Company will be pleased to forward periodically, copies of their publications and their regular publication *Service Suggestions*. The offices of the International General Electric Company, Inc., will be found in the advertising columns of this paper.

HILTON & CO.

This firm has now been taken over by Surendra Nath Ghosh who will carry on business at 109, College Street, Calcutta as heretofore.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to the *Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of the *Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

CHRONIC OSTEOMYELITIS IN LONG BONES.

By H. HALLILAY,

LIEUTENANT-COLONEL, I.M.S.,

Civil Surgeon, Simla.

In this country chronic bone disease, excluding that associated with syphilis, tubercle, new growth and mycetoma, commonly presents itself to the surgeon in one of two forms.

1. Massive necrosis of the whole or part of the original shaft which is enveloped in new bone with suppuration and sinus formation. This form is due to an attack of acute osteomyelitis, of which it is the sequel; it may be a source of intense suffering and discomfort to the patient and is liable to end in death from amyloid disease and exhaustion.

2. A chronic overgrowth and sclerosis of the shaft of the bone with or without the formation of sinuses. In this form there may be no outward sign of the sepsis which is lying in the heart of the bone, no sinuses, and no recurring abscesses which are so common in the first form.

Sequestrum formation may occur in this form varying in size from tiny spicules to quite considerable fragments.

The outstanding feature of both these varieties clinically is chronicity; they may persist for years, from early childhood to adolescence and from adolescence far into adult life until a more than usually severe exacerbation of sepsis or the onset of amyloid disease ends the patient's troubles by cutting short his or her life.

These cases are, from the actuarial point of view, "bad lives"; they have an enemy within the gates, always ready to seize an opportunity for the undoing of the host.

The history of such cases is a depressing one; it is usually a record of continuous or intermittent suppuration from a persistent sinus or sinuses alternating with the recurrence of acute trouble followed by operation and inevitable disappointment. After one of these interludes of pain,

insomnia and fever the flow of pus resumes the silent tenor of its way.

Many of these mournful legends are illustrated by pathetic ossuaries, fragments of necrosed bone which the sufferers have collected as melancholy souvenirs of epochs of intenser suffering in a life-time of discomfort. They will relate how on this, that or another occasion the bone was "scraped." Some of these scrapings were so obviously futile that the listener is reminded of Sidney Smith's famous reply to the little girl who told him that she was stroking her pet tortoise on its shell to tickle its back. He said, "You might as well stroke the dome of St. Paul's Cathedral to tickle the Dean and Chapter."

The surgical problem is the obliteration of a septic cavity with rigid walls. Some have attempted to solve the problem by adopting the methods employed by a dentist when dealing with a carious tooth, by filling the cavity with an amalgam of metals, or by the use of a decalcified sponge. Others have poured hot antiseptic pastes into the cavity; these set solid on cooling. Others again endeavour to effect the obliteration of the cavity by means of pedunculated grafts of muscle, a procedure obviously doomed to failure in the presence of any residual sepsis in the cavity.

The success attending these methods has been on the whole mediocre, but they have all one aim in common, viz., the obliteration of the bony cavity.

The method to be described here has this same object in view but attains it not by the introduction of a foreign body into a cavity, but by converting the cylinder of bone into a lath, nothing but the posterior thickness of the shaft being left. The free removal of all overhanging fragments permits the periosteal sleeve to collapse upon the residual strut of bone. New bone is rapidly laid down from the contiguous surfaces of bone and periosteum.

TECHNIQUE.

The conservation of the periosteum is essential in this operation. The incision is made on the surgical aspect of the bone, down to the bone through the periosteum for the whole length of the diseased area. If on exposing the bony cavity the disease is found to extend beyond the limits of the incision it should be extended in the same line, the periosteum being incised down to the bone.

The periosteum is then carefully separated from the bone with a rougine which should have a chisel edge of razor-like sharpness, so that an abundant supply of bone cells from the cambium layer is elevated with the periosteum. The subsequent rate of repair will be directly influenced by the care with which this operation is carried out.

The periosteum is separated up to the limits of the bone which it is decided to retain, always bearing in mind that it is essential to continue

the removal of bone until nothing is left but the two plane surfaces of the posterior aspect of the shaft.

With ordinary care, by working within the periosteal sleeve, the danger of damage to soft parts is negligible; with an adequate incision an ample exposure is secured and nothing need be done in the dark.

With all these operations for chronic sepsis in long bones free exposure and a good light are indispensable, for, if a focus of sepsis is overlooked the success of the operation may be jeopardised.

As soon as sufficient bone has been stripped of its periosteum the cavity of the shaft is opened by suitably planned cuts into the bone.

This may be done by an Allbee's saw or with chisel and mallet as desired. The electrically-driven saw saves much time and labour, but the necessary trimming of the shaft may be effected with chisel and gouge.

The surface of bone which remains is carefully scrutinised for areas of necrosis, sinuses, or actual perforations and all diseased tissue is energetically removed.

It should next be ascertained how far the periosteum and attached soft parts will glide in over the remains of the shaft.

Any projections interfering with this should be removed as it is important to reduce the number of dead spaces to a minimum.

When the operative area is in the neighbourhood of a joint great care must be exercised to avoid damage to the articular cartilage and the removal of bone should be so planned as to avoid too steep a descent.

This is particularly necessary when dealing with the tibia as if too steep a gradient is allowed it will be difficult to get the raw surface of the bone covered by the flaps of soft tissues and periosteum.

When all the diseased tissue has been removed we have a sort of keel of bone to which is hinged on each side of a flap of periosteum originally covering half the expanded shaft and preserving its original connections with the soft parts in relation to the bone, and in consequence maintaining its blood supply intact. These flaps are united in the line of the original incision by interrupted silkworm-gut sutures. This brings about the abolition of nearly all the dead space, any gap left at the upper extremity of the incision being plugged with gauze and allowed to fill up from the bottom.

If all the diseased tissue has been removed such cavities will become obliterated by a vigorous growth of close, healthy granulations and no more discharge will come away than is usual with any other healthy granulating surface. Increase of or persistence of discharge means some undetected focus of caries or recrudescence of caries in some part of the bone; this indicates subsequent minor operative interference.

The following cases will illustrate the results of this method; if the solidity of the residual

shaft of bone permits it the patient should be allowed upon his feet as soon as the wound is soundly healed or earlier if there is any delay in healing. Use is the best stimulus to bone growth.

To secure rapid healing and the best results the surgery must be very bold and radical; half-hearted operations are better left undone.

Illustrative cases.

Case 1.—P. S., aged 28. Duration of disease 1 year. Admitted on May 2nd, 1923. History of much pain and disability in the leg.

Operation.—June 10th, 1923. Great thickening and sclerosis of bone and caries in medullary canal extending nearly half the length of the shaft. Complete operation. Removal of all but a lath of bone so as to leave no overhanging edges; the separated leaves of periosteum came into good contact with the denuded bone. Convalescence was uneventful; there was abundant formation of new bone. The wound healed by first intention and the patient was discharged on July 28th, 1923.

Days in hospital after operation—49 days.

Case 2.—I. D., aged 22, admitted into hospital on July 3rd, 1923, with necrosis chronic osteomyelitis of the right tibia and leg riddled with sinuses. Duration 10 years.

Operation.—July 9th, 1923. Complete operation. Bone greatly sclerosed and thickened, rarefying osteitis, pus, no massive necrosis and no involucrum. All bone removed in anterior and lateral aspects, only a lath of bone left; the periosteum was carefully conserved. One small secondary operation was found to be necessary. The lower half of the wound healed by first intention but there was a small cavity left at the upper end which was not quite healed when the patient left hospital in October.

Stay in hospital after operation—86 days.

Case 3.—H. S., aged 12 years, admitted into hospital on July 30th, 1923, with much discharge, massive necrosis and involucrum.

Operation.—July 31st, 1923. Complete removal of all but the posterior layer of involucrum, cylinder of necrosed shaft removed,—it was lying free in the cavity of the involucrum; the periosteum came into good contact with the denuded area. The lower half of the wound healed by first intention but a cavity was left in the upper half which was plugged daily with plain gauze and granulated up. The patient was discharged on 24th September, 1923.

Stay in hospital—56 days.

Case 4.—J. R., aged 12, admitted into hospital on June 4th, 1923, with chronic osteomyelitis of the left tibia. Duration six months. Foul and copious discharge; general health very poor.

Operation.—June 12th, 1923. Removal of sequestra, all but the posterior part of the bone removed; periosteum in good contact with denuded area in lower two-thirds of the wound. Cavity left in upper third which was plugged. Discharge persisted so the wound was explored on August 21st, 1923, and a large piece of old necrotic bone was found under an overhanging ledge of bone; this was chiselled away, the piece taken away and all granulations were removed at the same time. The wound was packed with gauze and securely healed in its entire extent by November 10th, 1923. General condition much improved.

Stay in hospital—152 days.

Case 5.—A. H., aged 15. Chronic osteomyelitis of the left ulna. Duration 1 year. Ulna border of the arm was riddled with sinuses.

Operation.—July 10th, 1923. Large sequestrum, round, rather patchy involucrum, many sinuses; periosteum came into good contact with the denuded surface of the bone. The patient was discharged on August 29th, 1923, with good formation of bone and wound soundly healed.

Stay in hospital—50 days.

SOME POINTS IN THE ARTIFICIAL FEEDING OF INFANTS.

By E. H. VERE HODGE, M.B.,

MAJOR, I.M.S.,

Surgeon to H. E. The Governor of Bengal.

TAKE a child off the breast prematurely and his troubles begin. This is perhaps even more true in India than elsewhere. One is constantly seeing sick infants and hearing one story about them, that they thrived for three or four months on the breast but as soon as they were bottle-fed they lost weight and became sickly; cow's milk and all sorts of proprietary foods were tried in turn (without reference to their composition), but without success. It is the frequent repetition of this story that emboldens the writer to endeavour to summarise the generally accepted views on the values and methods of use of the available substitute foods. It is not unnatural that the lay public should seek to simplify the feeding of their infants by recourse to proprietary foods; modern advertisers are persuasive and persistent, the mother, with the virtues of some patent food constantly before her eyes, is apt to forget the fresh milk of the cow, the virtues of which are not broadcasted from every hoarding. Advice is sought and opinions so freely expressed as to the virtue of this or that food that it is well to form a balanced judgment of the relative values and defects of the two classes. Neither class is ideal, but it is only fair, when criticising proprietary foods to remember that we are comparing them with another substitute for the human infant and to bear in mind, on the one hand the defects of cow's milk and on the other to be certain that the results of misuse are not prejudicing us against patent foods.

By proprietary or patent foods, for the purposes of this article, some preparation of cow's milk whose sugar content is not higher than that of human milk, is understood, as it is only in selected cases of malnutrition that malted foods are admissible and even then their use is to be limited to the shortest time possible. This being the case, it is evident that both classes have faults in common, such as high protein content, deficiency of fat and resistance to digestion as compared with human milk. As regards digestibility, milk powders appear to have a slight advantage.

There are other faults, metrically minute, but nevertheless having far-reaching influence on metabolism.

Cow's milk containing, as it does, an excess of mineral salts neutralises a higher proportion of the acid of the gastric juice than does human milk. The practice of adding citrates to the milk will still further accentuate this fixing of the available acid, and the wisdom of such radical interference with the digestive cycle at its inception is debatable. True, the coagulability of the milk is reduced by the action of the citrates, which render some part of the calcium content not available, but at the same time the essential

hydrochloric acid is reduced, protein digestion is delayed, and the stimulus to the next link in the digestive chain is likely to be adversely affected.

Dunham (1925) on the contrary advises the acidification of milk with cider vinegar and claims to have had excellent results not only in normal children but in conditions such as pylorospasm which present grave difficulties. The writer having had no experience of this is unable to constitute himself an advocate but, on the same principle, has added small quantities of mineral acid to the feeds of infants when it seemed that the whole digestive tract was in a state of suspense for want of an initial stimulus; the results were encouraging.

Apart from interfering with digestion, any measure which tends to weaken the acid barrier of the stomach, already unstable in infants, is to be deprecated as opening the path to invading microbes.

A further defect is the low proportion of lecithin, an important constituent of brain and nerve tissue, and presumably required in the amount supplied by Nature. Fortunately this can be replaced by giving lecithin, one grain daily, until such time as the infant is able to digest egg-yolk.

To this point we have dealt with cow's milk at its best, that is, dairy milk from pasture-fed cows collected with scrupulous cleanliness, and with the faults common to it and to dried milk.

Of fresh milk there are still two sources, purchased milk or milk from the privately owned cow. The first is unthinkable, it would be necessary to autoclave it to make it safe; the second, though in the main satisfactory, must be subject to certain precautions. Firstly, the cow must be healthy and, if possible, tested with tuberculin. In view of the possibility of tuberculosis some authorities recommend the keeping of goats; secondly, the milk varies at different stages of lactation and a good fat content must be assured; thirdly, an important point is that the milk is liable to deficiencies in those very properties which are the reason for its election instead of dried milk.

The investigations of Dr. E. M. Luce (1924) into the effect of feeding and sunlight on the vitamine content and growth-promoting factors in milk have peculiar application to India. Incidentally she has suggested that the antirachitic and growth-promoting factors are separate entities and vary independently of each other, but the point which really concerns Indian milk is that both growth-promoting and antirachitic factors are poor when the cow is fed on dried fodder. This being the case, it is inconceivable that the plain-dwelling cow can be efficient in these properties in the hot weather.

In brief, many of the defects of artificial foods are also to be found in cow's milk and it is only the cow's milk of certain favourable conditions which can be held to be superior to the

dried substitute. At the same time, there can be little doubt that cow's milk of good quality offers the best substitute for human milk; it is easy of modification to something approaching breast standard by adding cream and sugar or by having recourse to the top-milk method. Further, it can be peptonised when the condition of the infant requires it.

The case for dried milk is that it is a clean food, easy to prepare and keep clean, constant in its proportions and reasonably easy to digest. Recent experiments have established the nutritive value of dried milk as superior to fresh, at any rate so far as laboratory animals are concerned. (Hartwell, 1925.)

The writer would quote from a well-known text-book by Dr. Eric Pritchard on "Physiological Feeding of Infants and Children."

"If a group of independent observers would take a series of infants and would feed them on dried milk modified to breast standard, and would comply with all other physiological conditions, I am perfectly certain that they would come to the same general conclusion that I have come to after fifteen years' experience in the management of nearly 3,000 infants fed exclusively on dried milk, namely, that if this method does not give as good results as any other method, it is not the fault of the milk but of the manner in which it is used."

There can be little question that proprietary foods are more often misused than not. Full directions are usually issued by the makers and one is inclined to think that they do their products an injustice by claiming too much for them. The common recommendation is that the baby from birth shall be fed on what is really the equivalent of cow's milk. If the baby thrives it is an accommodating baby and deserves the not infrequently earned distinction of having its photograph in the papers.

The grosser defects of cow's milk have been dealt with above, and these obviously apply with equal force to dried milk. Calculations from the standard tables issued with the food reveal a caloric value markedly below the requirements of the infant. Nowadays there are few adherents of the whole milk method of feeding, and it is unreasonable to invest dried milks with virtues not possessed by fresh milk.

Dried milk, therefore, requires the same careful modification that fresh milk does. It is now held that in dried milk vitamins *A* and *B* are present in sufficient quantities and that vitamin *C* is absent. At the same time, it is well to guard against a shortage by adding a small quantity of cod-liver oil as well as fruit juice to the diet. Failing these, as some infants seem incapable of digesting either, Metagen (Parke, Davis) will be found an efficient substitute.

To recommend the addition of cream to dried milks does not seem the soundest sense, as where there is good cream there also will be reliable milk, but the deficient fat may be made up satisfactorily with an artificial cream, such as that made from

peanut oil, which is issued daily in large quantities by the Great Ormonde Street Hospital.

Sugar must, of course, be added to standard and it is to be remembered, in drawing up diet sheets, that the caloric requirements of infants in the plains are markedly lower than those of the same infants in a cold climate.

In conclusion, the writer, while disclaiming an advocacy of dried milks as superior to fresh milk, would maintain that, where the milk supply is not above reproach, it is better to have recourse to dried milks from which satisfactory results may be expected, provided they are used with due appreciation of their constitution and of the physiological requirements of infants.

EXTRA-UTERINE GESTATION GOING TO TERM WITH A LIVING MOTHER AND CHILD.

By P. S. MILLS, M.B.,

LIEUTENANT-COLONEL, I.M.S.,

Civil Surgeon, Gaya.

A WOMAN, aged about 20 years, a Gwalah by caste, was admitted to the Pilgrim Hospital, Gaya, on 13th March, 1925, with the history that she had arrived at term of her first pregnancy, and that she had been in labour for three days.

The village midwives had done all they could, and as delivery did not take place, sent her to the Pilgrim Hospital, about 12 miles away, for treatment.

She was a sturdy and healthy woman, and menstruation had been regular until nine months previously, since when there had been complete amenorrhoea.

On admission it was found that there was a foetus in the abdomen, lying transversely with the head to the right. The remainder of the parts of the foetus could not be made out, and there was nothing in the abdominal signs to suggest ectopic gestation. The head was not more easily felt than normally. Foetal heart sounds could not be heard, but foetal movements were felt, although they were not very active.

Examination per vaginam showed a thick reddish-brown discharge in which were fragments of proliferated endometrium. It was not like the healthy red blood seen at the first show at the beginning of labour, but was much thicker, doubtless due to the shedding of the uterine decidua with the false labour that had been on for three days.

The cervix admitted two fingers, and the uterus could be made out lying somewhat to the right and about twice the size of the non-pregnant organ. Ectopic gestation was diagnosed.

The woman's general condition was very good, and it was difficult to believe that she had been in labour for three days.

Laparotomy was performed at once and it was found to be a broad ligament pregnancy on the left side. The sac was extremely thin, and it was surprising that it had not been ruptured by the manipulations of the native midwives. There were no adhesions and a live female child was extracted without difficulty. The pedicle was tied and the sac with placenta removed. The placenta was lying in front and to the left side, obscuring the back and breech of the child.

The mother unfortunately developed an abscess in the cellular tissue of the left side, but the pus was evacuated into the vagina and drained; she thereafter made an uninterrupted recovery.

The mother and the child left hospital well on 21st April, 1925.

There are a few points in connection with this case, and with ectopic gestations generally, which Major P. Fleming Gow, I.M.S., of the Eden Hospital, Calcutta, has been kind enough to point out. I quote them below:—

1. The age of the woman—20 years—is rather more than is common for a first pregnancy in the village class in India, suggesting the most common aetiological factor in ectopic gestation, viz., preceding inflammatory disease of the tubes, but there was no evidence of such in this case.

The appendages on the right side were healthy; on the left side they were removed with the sac. The left tube was elongated to 14 inches, 10 inches of which were attached to the margin of the placenta and the last four inches, with the abdominal ostium, were free of the placenta. The left ovary was healthy; no enlargement suggestive of a corpus luteum was made out in the right ovary.

In some cases of extra-uterine gestation it has been found that the corpus luteum is situated in the opposite ovary, indicating external migration of the ovum; there was no evidence of such in this case.

2. In broad ligament pregnancies the foetal parts can usually be made out with abnormal ease. In this case it was not so, and this is accounted for by the fact that the placenta obscured the body and breech of the infant.

3. The pedicle in this case was at the left cornu of the uterus and did not involve other parts, the placenta being quite separate from all the organs except the left tube. This made the operation a very simple one. The gestation was undoubtedly one originating in the proximal two inches, i.e., in the isthmus of the tube, the foetus burrowing downwards between the layers of the broad ligament, with the placenta remaining attached to the interior of the tube.

4. It is not infrequent for menstruation to continue for some time during an ectopic pregnancy, but in this case there was complete amenorrhoea.

5. It is not often that an extra-uterine foetus has such a happy fate. It is frequently absorbed while within the fallopian tube, and Mall has calculated that not more than 1 per cent. of all extra-uterine pregnancies will reach full term.

When the foetus has survived rupture of the tube, the diagnosis of broad ligament pregnancy is rarely made until false labour occurs, particularly so in India where there is so little ante-natal care. When false labour does set in, it is soon followed by the death of the child; this would certainly have happened in this case had laparotomy not been done without delay after the admission of the patient to hospital. Prompt laparotomy is the only real conservative treatment for unruptured extra-uterine pregnancy, since rupture may occur at any time and the patient may die before operative assistance is available.

It is only in very rare cases, however, that a normal living child is delivered from between the layers of the broad ligaments, and the operation in this case was comparatively easy as the foetal sac was free from adhesions and the placental site almost wholly within the tube.

It should be remembered that the removal is not always so easy, and if the placenta is spread over a broad area it may be better to marsupialise the sac and allow the placenta to separate piecemeal. If the placenta is partly separated it has to be removed, and if in removing the sac the uterus also has to be removed, the patient may die of hæmorrhage.

According to Whitridge Williams, the after-history of these cases is not abnormal, for the Johns Hopkins' statistics show that 38 per cent. of patients who, after an ectopic pregnancy, were left with a uterus, one ovary, and one tube, later became pregnant and were delivered at term of healthy children.

SALIENT POINTS ON SUPRAPUBIC PROSTATECTOMY AT ONE SITTING.

By M. D. DAVID, M.B., C.M., F.R.C.S.E.,
Civil Surgeon, Shwabo, Upper Burma.

THIS tabulated statement shows the details of five cases operated upon for enlarged prostate by the suprapubic method. Unfortunately, I was unable to get the first case photographed; the remaining four are represented in the picture.

It is noteworthy that these old men came in with "trivial" complaints, such as slight difficulty in passing urine, burning micturition, hæmaturia or frequency of micturition with chronically dilated bladders of which they were not aware. They usually showed all the signs of auto-intoxication, especially the neglected ones.

The details of method followed in these five cases are as follows:—

They were kept under observation for a week or so, their bladders relieved regularly at intervals of six or eight hours and washed out with potassium permanganate or boric once a day, and after their urine was tested they were treated with urotropin, salol, or benzoic acid, if necessary; their diet was milk and barley.

Photo. I.

Although operation in two stages is the ideal thing to do (i.e. (1), drainage of the bladder suprapubically through Pezzer's catheter; (2), enucleation three weeks later). I cannot persuade my patients to undergo the two-staged operation, simply because they consider that a second one has to be done due to the failure of the first. A preliminary course of calcium chloride grains xv in six to eight doses was given before operation; the bladder was washed out on the operation table; 8 to 12 ounces of clean boric or saline put in through a metal catheter and the bladder opened suprapubically. The bladder cavity was thoroughly explored as to size and shape of prostate, presence of stone, etc. Then with gloved left index finger in the rectum, enucleation was proceeded with by introducing the right index finger into the internal urethral orifice through the wound and scraping the mucous membrane which soon gives way. The lobes are enucleated easily, one by one or the prostate as a whole; if aided by the finger in the rectum, no force is necessary at all. Standing on the side rail of the operation table and leaning well over the patient helps a lot. If the enucleating finger is in the proper line of cleavage, between the prostatic capsule and the prostatic sheath of the pelvic fascia, the lobes shell out very easily indeed without much bleeding. Although the hæmorrhage is pretty profuse and frightening, it easily stops with fairly hot water irrigation either through the wound or

catheter. I have had no necessity to plug this space with adrenalin gauze. The bladder is drained suprapubically with a big-sized india-rubber tubing communicated to a bottle with some lotion, and Retzius' cavity by a separate small, short tube. I have not tried perineal drainage which is bound to do very well, as it will be in the most dependent part and will avoid absorption of foul urine and blood clot. This can be easily done by pushing a long bent forceps into the prostatic space through the wound, opening the perineum on its tip and drawing in a drainage tube. Even if this is done I am inclined to keep the bladder wound open as well with a drainage tube from below. The patient is kept in Fowler's position and the drainage tube discarded on the fourth or fifth day after operation. He is given plenty of fluids, barley, milk, soda, mist. diuretic and urotropin, benzoic acid or salol, etc. The bowels are kept open on the third day. The great thing is to prevent hypostatic congestion of the lungs by getting the patient to get up and get out on to an easy chair as early as possible after the danger of hæmorrhage passes away. In some cases recurring hæmorrhage does come on which may not stop due to the condition of the blood vessels and sloughing of the tissues owing to sepsis and cause the death of the patient. I resort to calcium chloride injections intramuscularly and I must say I have been fortunate to save all my patients, though I have not been able to prevent abscesses forming at the seat of injection even with every possible care and attention. Hæmostatic serum ought to help in such cases, also adrenalin pack after hot irrigation. I can remember an old patient saved in the Rangoon General Hospital with injections of morphia and, at the suggestion of a sister, iced rectal injections. He is still living to tell his tale and is a reporter of an important Rangoon daily paper. Personally, I avoid morphia as far as possible in these cases on account of the damaged condition of the kidneys, but I do believe it has to be resorted to when everything else fails to arrest hæmorrhage. After removal of the suprapubic drainage tubes, the wound is carefully and gently irrigated once or twice a day, the dressings changed several times a day, and the patient is encouraged to get about a bit carefully and on to an easy chair. He is allowed to have the food he cares for, augmented by plenty of fluids and barley water. About the 18th to 21st day he starts passing some urine by the urethra and the suprapubic wound rapidly heals up in another week or two and the patient is again as fit as a fiddle.

What has happened in the prostatic pouch is as follows:—First part of the urethra is

replaced by the collapsed fibrous sac consisting of a prostatic sheath of pelvic fascia communicating with the neck of the bladder above and membranous urethra below. This passage is later on lined by mucous membrane growing above from the neck of the bladder and below from the membranous urethra.

The severe cases were those in which the temperature continued very high causing delirium and prostration or were complicated by an underlying lung condition, e.g., pleuro-pneumonia or broncho-pneumonia.

It is in these cases that the drug (iodine) used intravenously has proved so beneficial in our

A NOTE ON THE VALUE OF IODINE INTRAVENOUSLY IN THE TREATMENT OF INFLUENZA.

By Asst. Surgeon C. P. V. SHUNKER, I.M.D.,
Superintendent, Central Jail, Bellary.

DURING the month of June 1925, there occurred at this Jail an epidemic of influenza resulting in the admission of 66 cases to hospital within a short period. All the cases were of the typical acute catarrhal variety (respiratory type) of the disease. Twelve cases were complicated by lung conditions, pleuro-pneumonia or broncho-pneumonia. There were no deaths.

My attention having been drawn to the value of iodine intravenously in septic conditions, the method was given a trial in the very severe cases when the usual remedies, e.g., sodium salicylate, cinchona, etc., had little or no effect.

hands. In fact we have been struck by the marked improvement in the general condition of such patients. Within 24 hours of the injection most of the patients passed from a condition of anxiety and distress into one of comparative comfort.

There is no danger attached to the method if the usual precautions are taken. The formula used was that of Dr. Chaudhuri as advocated by him in the *Indian Medical Gazette* for February, 1925, but instead of 3 to 6 minims as a dose, 20 minims were given in 10 c.c. of saline as the initial injection. If the temperature and general condition do not improve a second injection of 40 minims diluted to 10 c.c. of saline is administered generally within 48 hours.

In our series most of the cases were greatly benefited by one injection. Some of the more serious cases required a second and even a third

injection, while one case—the most serious of all that we had—received five injections.

Formula:—

Iodum	.. 1 drm.
Pot. Iodide	.. 1 drm.
Aq. distillata	.. 5 ozs. 2 drms.

The iodine is dissolved in the solution of potassium iodide in distilled water, previously prepared.

Roughly, 20 minims of the above solution contains $\frac{1}{2}$ grain of iodine.

Initial dose. 20 minims ($\frac{1}{2}$ grain iodine).

Second and subsequent doses. 40 minims (1 grain iodine).

THE MOSQUITO FACTOR IN THE MALARIA OF ASSAM TEA GARDENS.

By C. STRICKLAND, M.A., B.Ch.,

Professor of Medical Entomology, School of Tropical Medicine and Hygiene, Calcutta.

INTRODUCTION.

THE main object in here reproducing this paper which was read before the Assam Branch of the British Medical Association at its Jorhat Meeting on March 2nd, 1925, is to publish it with the illustrations which were given by lantern and to correct a few minor misapprehensions thereanent which have arisen.

The subject was the conclusions arrived at from a mosquito malaria survey of the tea gardens of Assam which the Endowment Fund of the School of Tropical Medicine was enabled to finance by the generous help of the Indian Tea Association. Further study of the detailed observations which have only recently been concluded may of course oblige us to modify the opinions expressed here, but in the meantime they are submitted for "necessary action."

I wish to repeat here that I owe a great deal to Lieutenant-Colonel J. W. D. Megaw, I.M.S., Director of the School of Tropical Medicine, for his sympathetic administration of the work undertaken, and to the officers and members of the Indian Tea Association for their help in every way. The work would have been impossible had it not been for the acceptance of the spirit of the scheme by the Medical Officers of the tea estates, for they placed all information at my disposal and every possible facility for collecting the data which I required.

THE ADVANTAGES OF A SURVEY.

While a malaria-prevention campaign without a previous survey can indeed be carried out by employing certain measures which are of general application, a survey has three advantages, enabling one to (1) find out if a healthy site be available; (2) localise the area in which prophylactic measures should be taken; and (3) choose the most appropriate measures to deal with the situation. The last item is very important because some anti-malarial methods not

being of general application might, if tried without knowing what situation is being dealt with, cause worse trouble. Take for instance, open earth-drainage; one drains a swamp and eradicates the species *umbrosus*, one drains another and introduces *maculatus* or *funestus*. In this connection Boyd says "all anopheline mosquitos are not carriers of the malaria parasites, and gross variations with regard to breeding habits are found among the different species of anophelines. Thus, it often happens that in a mosquito-infected district where malaria is occurring, only a small portion of the total mosquitos are of the carrier type, and these may have quite specialised breeding habits, so that general measures of mosquito destruction might miss them altogether. The first essential in any district is, therefore, to make a critical survey to ascertain what mosquitos are carrying the parasite and what their breeding habits are; after which, if feasible, steps specifically directed against the carrier species may be undertaken. To illustrate the diversity of breeding habits the following instances may be quoted:—*Anopheles maculipennis*, a well-known carrier, breeds chiefly in swamps and marshes and does not breed in running water, so that it can be attacked by draining the swamp. Conversely, *A. maculatus*, which gave rise to much trouble in the Federated Malay States, breeds in running water. Other things being equal, therefore, draining by open drains (the usual method) would not abolish but rather encourage the breeding of this species. Yet another, *A. stephensi*, is almost exclusively a well-breeder and can only be countered by screening or oiling the responsible wells. It can thus be seen that haphazard measures are almost bound to involve a waste of time and money, and may even render the last state of affairs worse than the first by taking away conditions under which harmless mosquitos were breeding and replacing them by others suitable to the propagation of carrier species" (1924).

On the same subject Sir Ronald Ross at a meeting of the Royal Society of Tropical Medicine (1924) stated how different species of mosquitos must be dealt with in different ways. He said "We must deal with each species on its merits"; to which dictum Major Austin agreed, and Dr. Ballfour and Major Austin both were of the opinion that it was necessary to make careful biological investigations before starting upon any anti-malarial campaign. Watson (1924) in this connection said, "Let me candidly admit that for some years we cleaned up the ravines in our hill-land in Malaya making the malaria worse. We had to adopt an entirely different method. Let me remind you too that in 1901 when the Federated Malay States Government gave me the money to clean up Klang, Dr. Braddon applied for money to clean Seremban, a town on the main range. Presumably he would have felled jungle and "trained" streams, and would have caused a big outburst of malaria in, at that time, a healthy

town. Had that occurred I can imagine the progress of malaria prevention in the Federated Malay States would have been seriously retarded as it has been in India by the experiment done in Mian Mir."

The fact that Watson started to preach this doctrine of the specific prevention of malaria in 1911 and that it is still necessary in 1925 for the Society of Tropical Medicine to reiterate it seems rather lamentable.

It will, however, be seen how important it is to do a preliminary survey. As Dr. Murphy of Sylhet has said very concisely "to obtain the most successful results with the most economical expenditure it is necessary that a preliminary detailed survey should be carried out."

PREVIOUS SURVEYS IN ASSAM.

From time to time other surveys than that which is the subject of the present paper have been conducted in Assam. Not all of them have been in tea-garden tracts, but I have included a consideration of some of them in this paper because of the general similarity of the terrain described with that of the tea gardens.

These surveys have been made at Lunding Junction by many medical officers in co-operation, the report being published by Lieutenant-Colonel T. C. McCombie Young, I.M.S. (1921); at Nalbari, Kamrup District, reported by Lieutenant-Colonel S. R. Christophers, I.M.S. (1922), Lieutenant-Colonel McCombie Young I.M.S., and Captain B. S. Challam (1923); at Pasighat by Lieutenant-Colonel McCombie Young, I.M.S. (1921); and lastly, at Doom Dooma by Sir Malcolm Watson (1924). An analysis of these reports has been made in conjunction with the data collected in my survey and details will be noticed below.

THE MOSQUITOS OF ASSAM.

Of the 42 known Indian and Malayan anophelines 15 have been found in Assam and of these 6, because of what is known of their activities elsewhere, must be on their face value suspected and will be the only ones considered here; with regard to some of the others, however, a mental reservation might be held pending further information.

The six are:—*umbrosus*, *jeyporiensis*, *aconitus*, *funestus*,* *culicifacies*, and *maculatus*.

A. UMBROSUS.

This species was one of those responsible for so much trouble in Malaya before Watson showed how to deal with it. We now know it is very easy to tackle; rough open earth-drainage, even through the jungle, is sufficient to eradicate it. It lives in pools or swamps in the jungle or in densely-shaded places, so that by merely cutting down the shade one becomes rid of it.

As it can be so harmful, the question arises as to the place it takes in the malaria problem in Assam.

I have caught it in several places in Assam jungles, for instance, in the swampy ground under jungle near to Lokra in the Balipara Frontier Tract, (fig. 1), and I have no reason to suppose it is not to be found in all similar situations.

FIG. 1.—*Daphla chang* in the jungle near Lokra.

But does it do any harm? I agree with Watson that in gardens which are well cleared such as in the Doom Dooma district the species is perhaps of no importance, nevertheless it is significant that of the estates along the Dibru or similar rivers, which he mentions as being so malarious, some are opposite the Dibru Forest Reserve. The evidence of the seasonal incidence of malaria in the gardens is also compatible with this being at least partly due to *umbrosus*, for being a swamp breeder it is probably much increased in numbers during the rains, when malaria is also more prevalent.

At Pasighat which Lieutenant-Colonel McCombie Young, I.M.S., surveyed, *umbrosus* was not incriminated but I am inclined to think on reading his description of the terrain that *umbrosus* may have been partly to blame. It seems to me significant that great improvement in health followed cutting down a belt of jungle 300 yards from the lines.

Then one must note too that at Lunding Junction where all anophelines except some breeding in the bed of a river have been got rid of and the spleen-index reduced from about 80 to 30 per cent., a community of sweepers living near the jungle boundary still have a high malaria-rate and a splenic-index of about 90, so Dr. Leitch tells me.

As a final point I would cite the ill reputation for "fever" that the Nambur Forest has for officers on tour.

In general I would give my opinion that any undrained jungle in relation to tea gardens should be considered dangerous until it has been proved not to be so.

* *A. funestus* = *minimus* and *listoni*.

A. MACULATUS.

McCombie Young in his Pasighat survey determined that *maculatus* was the cause of most, if not all, of the trouble. At Lumding, where it was found breeding in the sandy bed of the considerable river the Horu Langpher (fig. 2),

FIG. 2.—The sandy bed of Horu Langpher breeding *A. culicifacies* and *A. maculatus*.

it was not incriminated to the same extent by James, Young, and Fry; and as subsequent anti-malarial measures seem to have eradicated the other species one may conclude that *maculatus*, which still breeds in the bed of the river, is probably responsible for the spleen-index of about 30 per cent. which persists. I am indebted to Drs. Weldon and Leitch for my data.

Challam at Nalbari, in 1920, found no *maculatus*; in 1921, during October and November, a few; and in 1922, after April, some more. He concluded nevertheless that they were not the source of much malaria, in which view McCombie Young concurred. On the other hand, *maculatus* was one of the species which Watson considered to be a dangerous factor in the Doom Dooma gardens. He found it abundantly in January.

I did not find *maculatus* myself very often, only 17 times out of a total of 2,774 catches of all species, and of those most were found in hill-side streams where one would expect the species; however, the paucity of my catch is not surprising when one considers the general lack of suitable breeding places for it in most tea gardens. *A. maculatus* is essentially a stream breeder (fig. 3), or a drain breeder, so that where drains hold spring-water they may be dangerous; it is not a swamp breeder. Watson says, *A. maculatus* lives in the purest water, so it is found in hill-streams, springs at the foot of the hills and banks, and in *bhils*. It is never found out in large flat *pathars* (rice-fields) away from hills, but in narrow valleys in the hills; it may be found in the small *pottahs* or areas which are irrigated by clean water. It is highly sensitive to pollution, or its food is, for even daily washing of clothes at the

head of a small valley will drive the insect from the main stream."

With regard to Watson's conclusion that the species must be regarded as one of the chief causes of malaria in the Doom Dooma gardens, it must be remembered that he found it in the months January to March, and as this is not the malaria season its connection with *maculatus* must still be proved. No observer has yet reported it during the malaria season.

Watson says, and I agree, that the species is to be found breeding in pools in the beds of big rivers like the Brahmaputra, but that "big rivers as a rule are not associated with malaria": which proves that the mere fact of finding *maculatus* in any place is not evidence of any connection with malaria there.

The species having such a liking for seepage water is an additional argument against it being very prevalent in Assam or causing much trouble, for the land is generally low-lying and there is not much seepage; what there is will be found

FIG. 3.—*Maculatus* is a stream-breeder.

where the land is more hilly as in Cachar (fig. 4). In such places, in my opinion, it is more likely that *maculatus* is doing harm, although I found no direct evidence of it.

A. CULICIFACIES.

This species has been reported in the Nalbari and in the Lumding survey. At Nalbari it was found in June breeding scantily in rain pools in paddy-fields, but not much importance was ascribed to it. At Lumding it was found by Weldon in large numbers in a tank as well as in pools in the bed of the big river and much of the malaria was put down to it. Unfortunately the season during which it was found breeding was not mentioned.

Watson caught none of the species but in his conclusions thinks that perhaps it is of some importance.

Likewise, during my three months preliminary survey of the tea gardens in 1923, I found none. However there is no inherent improbability that *culicifacies* is a factor in tea-garden malaria. Watson and I caught none because we tried at the wrong season (October to March). The species is a pool breeder like *umbrosus*, so it should be looked for at the advent of the rains

FIG. 4.—*A. Maculatus* will be found where land is more hilly, as in Cachar.

when the malaria season is starting. It is a clean water breeder; seepage or fresh water pools in the beds of streams or drains in the uplands or where subsoil drainage is good are its natural habitat. It would not be found on low-lying lands like the *pathar* level, hence a place like Dibrugarh is not malarious. Drainage eradicates it as it cannot breed in running water.

A. JEYPORIENSIS.

This species, in the light of our present knowledge, need not be seriously considered.

I only found it on one occasion in South Sylhet; Dr. Meek has since sent (from Cachar) a number of specimens caught in August, but as no one during the previous surveys has reported it, it cannot be of any great epidemiological importance.

A. FUNESTUS (MINIMUS) AND A. ACONITUS.

I will deal with these two species together as they are closely related. It is not usual to find them on the *pathar* level; their habitat lies in streamlets of running water edged with grass, (figs. 5-7). The larvæ have the thorax particularly well developed, which enables one to distinguish them from most other anophelines with the naked eye. Watson says they are found in the clearest water, e.g., "in the *bhils*."

McCombie Young in the Lumding survey and Challam and McCombie Young at Nalbari decided that in these places *funestus* was the chief carrier, while Watson in Doom Dooma concluded that it was of the greatest danger to the tea gardens; he found it in abundance and of

adult anophelines caught in houses 45 per cent. were of this species.

FIG. 5.—Streams breeding *A. funestus*.

FIG. 6.—Streams breeding *A. funestus*.

FIG. 7.—Streams breeding *A. funestus*.

I found 136 breeding places out of 1,730 during September to November, 1923, *umbrosus* being the next among the malaria carriers with 29. The species was not found in comparatively non-malarious localities.

It is generally agreed then that this is an enemy of the first importance and this is equivalent to saying that the *streams and irrigating channels of the rice-fields are culpable* (figs. 8, 9).

FIG. 8.—The irrigating channel of a rice-field.

FIG. 9.—Rice-fields irrigated by a side channel, which harboured *A. aconitus*.

CONCLUSIONS REGARDING THE RELATIVE IMPORTANCE OF THE SPECIES.

Of the known malaria carriers which occur in Assam I have concluded then that *funestus* and *aconitus*, represented in the paddy-fields, are very dangerous; that probably during the rains *culicifacies* breeding in pools of pure water is also of danger; that *maculatus* breeding in spring-water cannot on present evidence be incriminated with

doing much harm; that *umbrosus* lurks in all undrained jungle which should be viewed with great suspicion; and that *jeyporiensis* takes no important part in the causation of the disease.

MOSQUITO CONTROL.

MEASURES NOT DEPENDENT UPON A MOSQUITO MALARIA SURVEY.

On the subject of mosquito control one may first consider those methods which are not dependent on a mosquito survey.

Sterilising the blood of the carriers of the parasite.—The carriers from whom the mosquito mainly becomes infected are the children, and every effort, I suggest, should be made to treat such children with quinine so as to prevent them infecting the mosquito. A similar principle is observed in the practice of protecting from mosquitos all persons with parasites in their blood, for instance, in screened hospitals or segregating the sick. Parasite parades might be held regularly, once a week, using Knowles' and Das Gupta's (1924) excellent thick-film method for discovering the parasite.

Quinine* unfortunately has many limitations, of which the outward symbol is the excessive malarial incidence of the estates. It is to be hoped that the chemists will soon discover something as effective for the malaria plasmodium as trypan-blue is for *Piroplasma canis*.

Protection from the bite of the insect.—For the European some protection is afforded by the use of mosquito boots and the European in Assam is to be congratulated on his general attention to such matters; but this does not protect other parts than the ankles. For this reason, I strongly recommend the use of mosquito-proofed houses or at any rate proofed dining-room and lounge. *And it is to my mind more important than anything else that clubs should be thus protected.* Nobody who has not lived in a screened house can appreciate its comfort (fig. 10). One objection that is often made against it, is that it is impossibly stifling in the hot weather. Certainly that is so if the screening is fixed, but if it is made to be opened up from sunrise to sundown, my experience is that it does not make the air appreciably hotter.

This measure is of course only applicable to the staff of the estates though I wonder if it would not repay the Companies to give their labour cheap and strong bed nets, starting with those who would apply for them. We all know how the cooly will get under a net except for his feet, but even then his chance of infection is much lessened (and his feet ought to be horny enough to look after themselves).

GENERAL METHODS OF MOSQUITO CONTROL WHICH ARE NOT DEPENDENT ON THE SPECIES OF MOSQUITO PRESENT.

1. *Water-tidiness.*—When any species' breeding-place is "tidied-up" (fig. 11) it is rendered

*I will deal in another place with the so-called quinine prophylaxis.

FIG. 10.—A mosquito-proofed bungalow.

FIG. 11.—Water-tidiness, clean-weeding paddy.

less suitable for the life of the mosquito because its protection and food is removed. In pools and ditches of slowly-running water this implies the clearing out of as much debris and foreign matter as possible, also the oiling and burning of all plant life; in streamlets it implies the keeping of the banks and edges clear of vegetation or facing them with concrete (fig. 12) or steps, and "training" or deepening the water-channel to such an extent that plants cannot grow.

Water-tidiness has been the *raison d'être* of the drains put in at Lumding where the old earth drains have been lined with a concrete invert constructed of reinforced concrete and deep enough to carry off the normal drainage and the banks above the drains have been shaped and smoothed down and curved.

FIG. 12.—Water-tidiness, concreting the bed of a hill-stream.

For water-tidiness a mosquito gang under an overseer should be employed.

2. *Subsoil drainage and filling.*—Subsoil drainage will not be discussed here as in Assam it is not "practical politics." Another general measure is filling, but this is expensive. The tank at Lumding was filled. The principle is the same as subsoil drainage, that is, the water is kept underground. In Orissa I have seen shallow natural nullahs, which are prolific breeding-places of certain malaria-carrying anophelines, filled in by the natives to level up the land for rice cultivation; an instance of economics and sanitation going hand in hand.

MOSQUITO CONTROL *vis-à-vis* CERTAIN SPECIES.

There are certain methods of mosquito control which are dependent on the species present.

1. *Open earth-drainage.*—Open drainage implies the confining of all masses of water within regular channels and a fall provided in order to enable the water to run away. There are, however, certain situations where such a scheme is impossible.

Drainage, strange as it may seem, does not appear on the schedule of "measures of general application." Three of the malaria-carriers prevalent in Assam,—*A. maculatus*, *funestus*, and *aconitus*—are stream breeders, the two latter fast-stream breeders, so what one does by confining collections of water into regular channels is to increase the pace or flow of the water and therefore make it easier for *maculatus*, *funestus* and *aconitus* to breed. Watson in 1911 demonstrated this; he drained his swamps, whereupon *maculatus*—which is not a swamp breeder—obtained a habitat to its liking and malaria was increased by the measures taken.* And there is no *a priori*

* Incidentally this example may dispose of the ridiculous hypothesis that a species of mosquito driven out of one type of habitat will establish itself in another.

reason to suppose that what happened in Malaya would not happen in Assam, or an even worse thing because here the species *funestus* is so prolific, while it is altogether absent in Malaya. There is no doubt whatever that it is chiefly in the drains dug by the native cultivators for irrigating purposes that *funestus* and *aconitus* are principally found.

There is, however, the possibility that the reduction of the area of water in a *bhil* may countervail the factor just mentioned and the sum-total of *funestus* output might be reduced: drainage systems are now being used with this idea by Watson to control *maculatus* and *funestus* in the Doom Dooma gardens.

2. *Oiling*.—This measure might be considered of general application except for the fact that in fast-running streams the film tends to flow away and collect in midstream so that its influence soon dies away on the grassy borders where *funestus** and *aconitus* are found.

The utility of oiling is really in inverse proportion to the rapidity of exchange of water in any breeding-place whether that exchange is due to surface water running away or is due to spring-water.

In streams I feel that the cost of this measure is out of proportion to the results and if water-tidiness is resorted to the same results would be much cheaper.

When one comes to consider the pool breeders there can be no doubt of the efficacy of oiling. *A. umbrosus* is essentially a pool breeder, as is *culicifacies*; so is *maculatus* if the pool is of spring-water.

In all such places oiling would be very effective, though in great swamps it is impracticable and they must be drained first. For oiling constant supervision is needed and the cost of the organisation would be high even in Assam in spite of (1) the proximity of the Assam oil-fields and (2) the discovery of the use of castor-oil for aiding the spreading qualities. Oiling has been discarded by the Corporation of Calcutta because of the human equation. Moreover where there is any rice cultivation oiling cannot be used.

Larvacides, which may be considered here, are mostly dangerous and possess no advantages over oil. But Balfour recommends for undrainable swamps a "marine soap" manufactured in Marseilles.

3. *Flooding*.—More might be made of this measure. The practice is to throw a dam across a valley when the effect is to create a large body of deep comparatively still water where swamps or running streams existed before (fig. 13).

Danger may ensue at a later stage when silting takes place to such an extent that water plants may take root, or when there is a mass of certain floating water plants. Moreover, seepage below the dam may be a source of danger.

* *A. funestus* lives at the edge of really fast-running streams while *maculatus* lives in little pockets or bays.

FIG. 13.—"Drowning" a dangerous ravine (Shillong).

At a still later stage the embankment may hold up a solid mass of silt over which the original flow is distributed if it is not retained beneath the surface (fig. 14).

FIG. 14.—At the bottom of the steps is a bed silt held up by a stonework dam.

4. *Jungle-growing*.—This measure is of limited application as there is the danger of *umbrosus* behind it. In Malaya, in parts of the country where *umbrosus* is not found, among the inland hills, where are situated most of the rubber estates, it is the best method of preventing malaria (fig. 15) and it is now, I believe, the law that a permit must be obtained from the Health Department before any jungle is cut. With regard to the "coastal hills," where *umbrosus* is found, I suggested in an unpublished report to the Government of the Federated Malay States (1916) that the *umbrosus* and *maculatus* danger could both be averted by digging drains through the jungle, the only alternative being subsoil drainage which is very expensive.

In Assam I have no reason to suppose that the same procedure would not be perfectly effective, i.e., filling up the "*hulas*" and "*kals*" with

FIG. 15.—The best way of preventing malaria, jungle-growing.

jungle after draining them and then neither *umbrosus*, *maculatus* nor *funestus* could breed. Of course rice cultivation would be precluded by this measure.

5. *Jungle-clearing*.—This measure should certainly be resorted to where, after the land is cleared, *culici-acies* and *funestus* will not breed. If this would take place the health would probably become worse. Presumably Dibrugarh and certain tea gardens on the so-called *pathar* level were malarious when they were under jungle, but they have been cleared and drained for settlement or planting and are now comparatively healthy. This is what happened in Malaya where Watson had such great success with his early efforts in 1901.

That completes the summary of the more important operations that can be undertaken in a mosquito-control campaign.

Measures of general application:—

1. Therapy.
2. Protection from the insect.
3. Water-tidiness.
4. Subsoil drainage and filling.

Measures that depend on the findings of a mosquito survey:—

1. Open earth-drainage.
2. Oiling and larvacides.
3. Flooding.
4. Jungle-growing.
5. Jungle-clearing.

SUMMARY.

Reviewing the opinions expressed above, one might say that screening houses and especially clubs is very desirable and that an organised attempt at sterilising the blood of the children should be made.

While with regard to other measures, except in places on the '*pathar* level' where clearing jungle should be all that is necessary, one is confronted by something of a jigsaw puzzle which is complicated by the fact that oiling, jungle-growing and flooding are incompatible with rice-growing.

If rice-growing need not be considered then the situation can easily be dealt with by draining and oiling combined, flooding, or by jungle-growing combined with draining.

On the other hand, the only preventive measures compatible with rice cultivation which may be successful are the general measures (except subsoil drainage); none of the special measures given above would be applicable.

The bed-rock alternative is, therefore, which is preferable, the rice cultivation and only perhaps a mitigation of the malarial prevalence, or the rice given up and a non-malarious labour force. I expect many estate managers would say "let us be content with trying to mitigate our condition by means of the general methods." On the other hand, Crawford says "some discipline there must be on every garden in the interests of health."

But the planter must clearly see that if he wishes to control his malaria either on economic or humanitarian grounds he has got to interfere with his rice cultivation.

This rice cultivation seems to be something of a fetish, for in "*Castes and Tribes of India*" published by the Indian Tea Association, one reads the following passage:—"Facilities for the acquisition of land have in the past been held out as decided attractions to estates which are in the position to grant holdings, either free or at a nominal rent, to the permanent labour force. This factor still, undoubtedly, carries great weight with potential emigrants, but at the same time many instances could be cited, particularly in Upper Assam where *khet* land has never been available, yet labour continues to flock to the estates in all seasons. It might be argued that such concerns are in this fortunate position owing to their strong connections in the recruiting districts, but when we consider the favourable economic conditions that have obtained in the districts during the last three seasons and the fact that sirdars of other estates, having the attraction of *khet* land to offer, have also been endeavouring to recruit, but with comparatively indifferent success, we are forced to the conclusion that the attractiveness of an estate lies, not so much in the offer of material amenities but in a feeling of confidence and faith in the management, in brief, the personality of the Manager."

I have myself seen that many of the gardens in the Doom Dooma District have no *dhan-khet* land and yet the Doom Dooma gardens must procure coolies, for are they not veritable El Dorados? The coolies there seem to be content with patches of *ausdhan* and vegetable gardens, not to mention churches and hospitals with bed

sheets. I ask whether all gardens cannot get on as well as the Doom Dooma gardens, and if not why not?

Doubtless there is no answer, but at the same time let me, for the sake of argument, accept the deep-seated feeling that exists in the matter and see whether anything can be done to cope with the difficulty. The following suggestions might be made:—

(1) That coolies be given their *dhan-khet* at some distance from the lines and the intervening land not rice-cultivated, and the lines concentrated so as to reduce the total non-cultivated area. I am told that the coolie likes to see his rice growing under his very nose, but on the other hand a prominent planter of the Jorhat District, in response to a demand from me that the planter himself should put up suggestions as to how the difficulty should be met, informed me that coolies would be quite content to have their *khets* some distance away. This view seems borne out by the fact that coolies will sometimes leave their *khets* and *bustees* for long periods to work on estates, only returning for the harvest.

If the lines then be concentrated on one side and *dhan-khet* parcelled out to the coolies as far away as possible, the intervening area can be treated to the special measures which are necessary, either flooding, jungle-growing, or draining and oiling.

(2) If that suggestion be not liked another to be submitted is based on our knowledge that it is the small *hulas* which are particularly dangerous, therefore, I would ask that the cultivation of small *hulas* only be given up and if that be not admitted, that at least the very dangerous irrigating channels may be dealt with in accordance with the general principles laid down, though I am afraid the results would be but meagre.

We have now seen whatever is strong or weak in the position, if mosquito control is aimed at. In general, I do not agree with Boyd, who has written:—"The simplicity of the theory, i.e., mosquito control, is too often outshone by the complications encountered in its practice. The problem bristles with difficulties which may be so great as to throw the matter out of court on the ground of impracticability."

It is, I hold, a fact that the problem, in no place where there has been a will to succeed, has presented insuperable difficulties, the only real difficulty having been the finding of money.

NON-MOSQUITO-CONTROL MEASURES.

1. *Quinine prophylaxis*.—One must now consider whether that famous prophylactic measure—quinine administration—would be preferable, i.e., quinine given to the whole labour force to prevent their becoming infected by mosquitos. The problem has been analysed by Dr. Hermitte in an address to the Assam branch of the British Medical Association. He came to the conclusion that quinine prophylaxis is efficacious and recommended two doses a night to ensure perfect results as quinine is excreted

8 hours after its ingestion but that only one dose would do a lot of good. On the other hand Dr. Forsyth in his carefully-controlled experiment at Kacharigaon found that with such a system as one would use in ordinary practice it produced no good results.

Hermitte did not mention the very carefully conducted experiments conducted by army officers at Salonika during the war. I think that if British army officers with highly disciplined troops under war conditions came to an adverse conclusion in the matter, their opinion should be regarded as final. Watson's opinion is that for prophylaxis no amount of quinine is of any avail to stamp out the disease. Malaria will not be eradicated unless some medicine vastly more effective than quinine is discovered or mosquitos are destroyed.

In general, therefore, it may be concluded that quinine prophylaxis does not offer sufficient inducement to us to use it rather than mosquito control.

2. *Site selection*.—Site selection is an important rival to mosquito control, but it is expensive. It requires a careful malaria and mosquito survey and a careful calculation as to whether the cost of moving houses, lines, etc., to a new site would be less than mosquito control measures. Certainly, however, when new habitations are being built one should choose the site most carefully and the medical officer should be the first and last man consulted.

SUMMARY.

When comparing the possibilities of mosquito control measures with others, one may summarise therefore that, except for site selection, mosquito control is best. Bassett Smith thinks that the method of destroying the mosquito carrier is evidently a practicable one but that it demands a large amount of co-operation on the part of those whose land is concerned. With intense optimism much can be done. Watson, however, states more forcibly that nothing but mosquito control can give the desired results.

ACCESSORY MEASURES.

There are certain measures which are quite ineffective in themselves as anti-malarial agencies, but which nevertheless are very important in the general campaign.

1. *Education and propaganda*.—Education and propaganda amongst the directors, the shareholders and the coolies is required.

The cooly, I believe, on some gardens is treated to a cinema show and perhaps he could be "got at" in this way by suitable propaganda.

As for the managers and directors, they have only to be shown reasonably and lucidly what has been accomplished elsewhere to be ready to furnish the sinews of war. In fact they seem to want usually very poor arguments to persuade them to pay up. They are, of course, nervous lest experiments should be conducted and prove costly failures, for unfortunately money spent

on the prevention of malaria has not always been repaid. One way of reassuring them would be, I think, for the Assam branch of the British Medical Association to proceed by resolution from time to time on agreed-upon measures which may be confidently recommended to the public. One resolution for instance might be that in the future lay-out of a garden the medical officer should be consulted; the present lay-out of some gardens showing the necessity for such a proposal. I am sure the directorates would feel that such a proceeding protects them from faddists. I could cite an instance myself of how the executive in Malaya was let down by a highly placed medical officer who thinking, *qua* the lady-novelists, that mangrove forest was deadly got money for cutting it down. He acted in quite good faith, but we now know that such a measure converts a healthy place into an unhealthy one.

We therefore have to educate the people who provide the money. Watson has said that most of his life he had spent in fighting the men who were preventing him from fighting the mosquito. I am very glad to see that something more than virtue has now been his reward.

It now therefore only remains for the directors to vote a large sum of money for propaganda among themselves.

2. *Financing anti-malarial measures.*—I am very strongly of the opinion, which I see has also been expressed by Watson, that the cost of anti-malarial work should not effect the commission of the staff of an estate. If it is made to do so, the practice will act like a dead weight on all the efforts of those who are trying to do some good.

3. *Technical education of the Doctor Babu.*—I think it is, an excellent idea that prompts Dr. Hermitte with the sanction of his directors, Messrs. Williamson, Magor & Co., Ltd., to send his doctor babus in a never-ending stream to the School of Tropical Medicine in Calcutta. Every doctor babu ought to have a microscope and know how to use it. If he went to the School of Tropical Medicine he would learn microscopical technique and how to identify mosquitos and parasites.

The school short course is admirably adapted to meet the needs of the tea estates doctor babus; and I am sure that the Director will give the fullest consideration to any suggestions which may be made by the Assam branch of the British Medical Association for making it even more suitable.

4. *Research.*—This must of necessity be largely left to institutions equipped for the purpose. One research suggested above was the looking for chemical compounds which would be better than quinine for clearing the blood of the parasite. The School of Tropical Medicine fulfils such a function and as it is largely dependent on public contributions, it is to be hoped that these will not be stinted.

CONCLUSION.

I have now surveyed the main points in the malaria problem in the Assam tea gardens and I hope I may have carried the reader with me in my argument.

If we are agreed, it is not likely that the planter will lag behind. His chief problem now seems to be the procuring of sufficient labour. As Crawford says, "To get, and still more to keep, labour is becoming yearly a more and more vital factor." Tea has to compete with the industrial concerns and also with plantations in other countries—Ceylon, Malaya, etc. In the competition Crawford says "The comparative attraction of particular estates will exercise an increasing influence on the labour supply"; the healthiness of a place "where the water is good" is undoubtedly such an attraction. I have myself seen how easy it has been for the healthy rubber plantations in the Federated Malay States to obtain coolies as compared with the unhealthy estates. While coolies on the healthy coast land were getting from 24 to 30 cents a day those in the malarious uplands took 60 to 80 cents.

Countries like Malaya and Ceylon have certainly paid more attention to sanitation than has India in general, so they have obtained a lead in the race which should now be reduced by Assam. It does seem lamentable that a quarter of a century after Watson started his work in Malayan plantations that a start has only just been made in Assam. All the more credit to the Associated Doom Dooma Companies and to Messrs. Duncan Bros. for being the first to make a move.

A development of the labour situation has come about during a generation of planting in that it is now seen that a sufficient labour force may perhaps be brought up on an estate. There is a growing labour force of 1,000 children, aged from 2 to 10 years, on Alinugger Estate in Sylhet. But this is a healthy estate and I doubt whether that would be possible in a highly malarious locality. As Watson says, "Quite apart from the sickness among the men, the women are concerned with the sickness and loss of their children, and where the greatest primal instinct—the maternal instinct—is thwarted, there can be no rest or stability among a people. Loss of, and sickness amongst, children unsettle the women; they blame the water, the food, the air, ghosts, spirits and other more or less real or imaginary causes. They instinctively seek to flee from the place, and what the woman thinks to-day, the man thinks to-morrow. They hear rumours and reports of healthier places and better pay, and as Mr. Ramsden told me, coolies leave here to seek employment elsewhere, but few or none come up here from lower down the valley. On the other hand, if her children are well and healthy a woman is generally loath to move, as she fears for her children in a strange place."

I conclude by saying myself that the motto for the combat should be "save the women and children."

THE TREATMENT OF MALARIA WITH PERACRINA 303.

By WILLIAM FLETCHER, M.D.,

*Institute for Medical Research, Kuala Lumpur,
Federated Malay States.*

THE MAKERS' ADVERTISEMENTS.

THE Haco Company of Berne, the manufacturers of Peracrina 303, have been kind enough to furnish me with a supply of this preparation for the treatment of persons suffering from malaria. They have sent me, in addition, a number of letters and pamphlets describing Peracrina and its employment in the treatment of malaria. Among these pamphlets were the "Therapeutic News" edited by the Haco Company and a report by Dr. J. Walker on the treatment of malaria with Peracrina, which was published originally in the *Archiv für Schiffs- und Tropen-Hygiene*.

The following information was contained in the pamphlets:—When Dr. Walker went out to the famine districts of the Volga, with the Swiss Red-Cross, the Haco Company gave him a supply of Peracrina to be used as an intestinal antiseptic. It did not prove to be of value for this purpose but to the surprise of the physicians attached to the expedition "it was found to be at least equal to quinine in the treatment of malaria."

The makers describe Peracrina 303 as "the chemical compound of an acridine dye stuff with a specific albuminate prepared according to a patented process. It is made up in sugar-coated pills each containing 7.7 grains." The dose recommended is eight pills per diem for children between nine and sixteen years of age, and

twelve pills a day for adults; but it is added that "small doses of Peracrina have worked with great success, very serious cases of adults and older children have been cured by doses of two to four pills." It is recommended that the pills be taken before meals at the rate of two pills at a time. The Haco Company advertise that Peracrina does not speedily reduce high temperature, but, if systematically employed, it cures malaria completely and permanently. A complete course of treatment lasts from three weeks up to three months, for it must be continued for a fortnight after an examination for plasmodia in the thick blood film has given a negative result. It is sometimes observed that during the first three weeks of treatment, the blood test shows an increase of plasmodia and during the same period the temperature has a tendency to rise occasionally. These symptoms need not cause anxiety. The Haco Company, Ltd. are willing to give to every physician the opportunity of judging for himself. Upon receipt of a money-order for two pounds, 400 Peracrina pills in two registered sample-packages will be sent to you. They should be sufficient for the treatment of an average test case of chronic malaria."

Dr. J. Walker claims to have treated seventy-two cases successfully with Peracrina, and, as illustrations, he reproduces the clinical histories of three cases, namely, Dollimanowa, Peredumowa and Assuna.

Case 1.—Dollimanowa. A case of acute benign tertian malaria. Peracrina was administered from the outset, and the treatment was continued for more than three months. The patient had six paroxysms in the first fortnight, the last was on the fourteenth day. She had no more fever during the rest of the time she was kept under observation, but malarial parasites were found at each of twenty-one examinations made during the first eighty-six days of treatment; the last occasion on which they were found being the eighty-sixth day. During the next eighteen days three examinations were made with negative results.

Case 2.—Peredumowa. A case of chronic benign tertian malaria. This patient had occasional attacks of fever up to the sixteenth day of treatment. The blood was examined twenty-nine times during the first two months, with positive results on twenty-one occasions. Schizonts were found on the sixty-second day of treatment. No parasites were found during the next fifteen days.

Case 3.—Assuna. A case of mixed tertian malaria. The patient had occasional attacks of fever up to the forty-ninth day of treatment. The blood was examined twenty-six times during the first eighty days, with twenty positive results. Trophozoites were present on the seventy-eighth day. Three negative examinations were made during the next thirteen days.

A CRITICISM OF THE ADVERTISEMENTS.

(1) *The composition of Peracrina 303.*—The makers state that Peracrina is a chemical compound of acriflavine with a specific albuminate. The pills which I received from them consist of a soft, brown, granular substance enclosed in a brown, sugary coating. When some of the granular substance was put into water, it did not

dissolve but the water became a fluorescent, yellowish green. The urine of patients, who are taking Peracrina is similarly coloured. When the pill mass was examined under the microscope it was found to consist of yeast cells, stained yellow. There were a few round starch grains mixed with the yeast cells. Several pills were examined and they were all found to consist of yeast. The cells were dead, they would not grow on laboratory media. The makers' description of Peracrina as a chemical compound with a specific albuminate appears to require modification.

(2) *The cost of Peracrina.*—The makers say that four hundred pills are necessary for the treatment of an ordinary case of malaria a treatment which occupies three months. The retail price in Singapore of a bottle containing a hundred pills is \$6, or fourteen shillings. Four hundred pills would, therefore, cost \$24, or two pounds sixteen shillings. This is much more expensive than quinine. The retail price of quinine sulphate is \$1-25, or two shillings and eleven pence, an ounce; and an ounce is sufficient for the treatment of an ordinary case of malaria. If quinine were given at the rate of 20 grains a day, for three months, about four ounces would be used and the cost would be \$5, or eleven shillings and eight pence. It is evident from these figures that the high price of Peracrina puts it beyond the reach of all but the rich. It is too expensive for use in hospitals or for the treatment of labourers on rubber estates or tin mines.

(3) *Dr. Walker's results in the treatment of malaria.*—The duration of the fever, in the three examples selected by Dr. Walker to illustrate successful treatment by Peracrina, was fourteen days in the first case, sixteen in the second and forty-nine in the third. Malaria parasites were found up to the eighty-sixth day in the first case, the sixty-second in the second case and the seventy-eighth in the third. As the treatment was continued for at least a fortnight after all parasites had disappeared, which is in accordance with the advice of the makers of Peracrina, it follows that the average duration of treatment in these three cases was eighty-nine days. People will not continue to swallow eight or twelve large pills every day for such a long period—(those supplied to us weighed ten grains a piece)—unless they are kept under the closest supervision; few patients can be observed and treated for so long. Malaria patients in this country, usually leave hospitals in less than ten days.

Very few people, at the present time, have followed the course of untreated malaria over a long period. In his book, "Malaria at Home and Abroad," Colonel S. P. James gives the charts of three Indians, suffering from untreated malaria, whose temperatures were recorded for several months. No one who compares the charts of these untreated Indians with those illustrating Dr. Walker's Peracrina cases, can fail

to see their resemblance. As James says, "in the great majority of cases of uncomplicated malaria the general course is towards recovery." The administration of Peracrina may have had nothing to do with the eventual disappearance of the parasites in Dr. Walker's three cases.

Dr. Walker's reports show that the treatment takes too long to be generally useful, and they fail to prove that Peracrina exerts any influence on the malaria parasite.

CLINICAL TESTS OF PERACRINA IN KUALA LUMPUR.

Through the kindness of Dr. E. A. O. Travers, the Medical Officer in charge of the District Hospital in Kuala Lumpur, I was able to give Peracrina to eighteen men who were suffering from malaria. I was not able to detain these people in hospital for more than ten days or a fortnight, nor could I keep them under observation after their discharge; it was, therefore, impossible to give them the three months' treatment recommended by the Haco Company.

The object of this inquiry was to determine if Peracrina could be used in the hospitals of the Malay States, instead of quinine, with equally good results in the cure of an attack of malaria. The question of permanent cure cannot be investigated accurately in a country where it is seldom possible to follow up a case after treatment or to insure against re-infection.

The eighteen patients were all labourers from rubber estates or tin mines. Fifteen of these were Tamils and three were Chinese. Six were suffering from subtertian malaria, six from benign tertian, five from mixed tertian and one from quartan. Eight pills a day were as many as we could persuade the patients to take. The average weight of the men was 101 lbs., consequently this dose was equivalent to twelve pills given to a man weighing 150 lbs., and twelve pills a day is the dose recommended by the makers. The pills were given to the patients in the laboratory. Blood films were examined twice a day and, at the same time, the urine was inspected for fluorescence and tested for quinine and albumen. This was done by my assistant Mr. Kandiah and myself.

The patients were divided into two groups. The first group comprised nine patients who were treated with Peracrina alone when they were first admitted to hospital. Quinine was not given to them until its administration became imperative. These cases were Nos. 6, 7, 8, 9, 11, 15, 16, 17, 18. In all of them, except No. 8, the number of parasites either increased or remained stationary and it became necessary to give quinine.

The second group of nine cases, Nos. 1, 2, 3, 4, 5, 10, 12, 13, 14, were given quinine at the commencement of treatment, either alone or in combination with Peracrina. As soon as the parasites had disappeared, quinine was discontinued and Peracrina was given alone. In two

cases, Nos. 4 and 5, there was no relapse while Peracrina was being given, but they were under observation for only five and eight days, respectively. In the remaining seven cases, Nos. 1, 2, 3, 10, 12, 13, 14, the parasites multiplied when the quinine was stopped and Peracrina was powerless to prevent relapses.

Most of the patients had suffered from former attacks of malaria. They had taken quinine then and they knew that it could relieve them. Eight patients who relapsed under Peracrina refused to continue taking it and asked that they might be given quinine instead.

There was no evidence, from the experiments, that the drug had any effect upon malaria parasites.

DETAILS OF THE TREATMENT OF EIGHTEEN PATIENTS WITH PERACRINA.

Case 1.—Tamil. Weight 70 lbs. Disease, subtertian malaria. This patient was given a week's treatment with cinchonine, in doses of seven grains twice a day. The temperature became normal on the third day and all parasites had disappeared by the end of the week. On the eighth day cinchonine was discontinued and Peracrina was given instead. There was no fever until the seventh day when a relapse occurred and trophozoites reappeared. They increased rapidly until there were more than one parasite in every two fields, by the nineteenth day. The Peracrina was then stopped and fourteen grains of cinchonine were given twice a day in its stead, with the result that there was no fever after the second day and no trophozoites after the third.

Case 2.—Tamil. Weight 100 lbs. Disease, subtertian malaria. Five grains of cinchonine were given twice a day together with Peracrina. The temperature became normal after two days' treatment and no trophozoites were found after the third day. Cinchonine was stopped on the fourth day and treatment was continued with Peracrina alone. Parasites reappeared on the sixth day, when there was an average of two in every hundred fields examined. By the tenth day there were twenty times as many and treatment with cinchonine was resumed, in doses of twenty grains twice a day, with the result that the parasites disappeared within three days.

Case 3.—Tamil. Weight, 96 lbs. Disease, mixed tertian malaria. Cinchonine was given in doses of ten grains twice a day. There was a heavy infection in this case but both the fever and the parasites had disappeared by the fifth day. Cinchonine was then discontinued and Peracrina was given instead. Subsequently a few trophozoites were found almost every day and they were present on the twelfth day, when the patient refused to continue the treatment.

Case 4.—Tamil. Weight, 98 lbs. Disease, subtertian malaria. Cinchonine was given in doses of ten grains twice a day. There was no fever after the second day and no trophozoites were found later than the third day. On the sixth day cinchonine was stopped and Peracrina begun. No relapse had occurred when the patient left the hospital five days later.

Case 5.—Chinese. Weight, 110 lbs. Disease, benign tertian malaria. Two five-grain doses of cinchonine were given together with Peracrina. This was a very light infection; after two days' treatment the cinchonine was stopped because neither fever nor parasites were present. Peracrina was continued until the tenth day when the patient left the hospital. There was no relapse during that period.

Case 6.—Tamil. Weight, 90 lbs. Disease, mixed tertian malaria. Peracrina was given alone for seven days, but during this time the subtertian parasites increased

instead of diminishing in number. On the eighth day two nine-grain doses of cinchonine were given because the temperature was 103° F. and there were about thirty rings in every hundred fields. Peracrina was continued until the fifteenth day but the trophozoites increased, the temperature rose, the patient became worse and he refused to take the drug any longer.

Case 7.—Tamil. Weight, 105 lbs. Disease, benign tertian malaria. Peracrina was given alone. When the patient was admitted to hospital there were about twelve rings in a hundred fields. From the fourth to the seventh day no trophozoites were found; but on the eighth day there was a relapse with fever and parasites, and the patient refused to continue taking Peracrina.

Case 8.—Chinese. Weight, 130 lbs. Disease, benign tertian malaria. This patient had a mild attack. He was given Peracrina alone. The parasites disappeared by the sixth day and on the seventh he left the hospital.

Case 9.—Tamil. Weight, 112 lbs. Disease, mixed tertian malaria. Peracrina was given alone. Parasites were still present on the fifth day, when he refused to remain in hospital.

Case 10.—Tamil. Weight, 107 lbs. Disease, subtertian malaria. Parasites were present in large numbers; consequently cinchonine was given in ten-grain doses together with Peracrina for a couple of days. By the third day the number of parasites had diminished, the cinchonine was discontinued and Peracrina was given alone. The parasites increased rapidly and it became necessary to give cinchonine again on the fifth and sixth days. This checked the multiplication of the parasites once more, but as soon as the cinchonine was withdrawn they increased again. On the ninth day Peracrina was discontinued and a course of cinchonine was administered with the result that the parasites disappeared in a few days.

Case 11.—Tamil. Weight, 95 lbs. Disease, benign tertian malaria. Peracrina was given alone for eight days. During this time the patient remained in the same condition. Parasites were found in his blood at every examination and at the end of the period he refused to continue the treatment.

Case 12.—Tamil. Weight, 120 lbs. Disease, subtertian malaria. As this was a rather heavy infection with subtertian parasites—200 rings in 100 fields—quinine was given along with the Peracrina for the first two days. On the third day there were only three parasites in a hundred fields; consequently the quinine was stopped and Peracrina continued alone. On the eighth day the parasites had increased to 580 in 100 fields and the patient asked for quinine. He was given three twelve-grain doses which reduced the number of trophozoites once more and Peracrina was administered alone until the fifteenth day. By this time the parasites had increased again, so the Peracrina was discontinued and the usual treatment with quinine was given in its place.

Case 13.—Tamil. Weight, 100 lbs. Disease, mixed tertian malaria. Twelve grains of quinine hydrochloride were given twice a day, together with Peracrina, for a period of two days. The quinine was then discontinued and Peracrina was given alone. The malaria parasites, which had disappeared on the third day as the result of the quinine treatment, returned on the tenth day in spite of the Peracrina and the patient refused to remain in hospital.

Case 14.—Tamil. Weight, 90 lbs. Disease, subtertian malaria. This patient was given two twelve-grain doses of quinine, on the first day, together with Peracrina. The quinine was then stopped and Peracrina was given alone. There were a few parasites present on the fifth day, when the patient insisted on leaving the hospital.

Case 15.—Chinese. Weight, 105 lbs. Disease, quartan malaria. No quinine was given to this patient for the first ten days of treatment, during which time Peracrina was administered alone. At the end of this period trophozoites and schizonts were still present and the patient was put on a course of quinine.

Case 16.—Tamil. Weight, 93 lbs. Disease, benign tertian malaria. This patient had a very light infection; at the beginning of the treatment with Peracrina one parasite was found in every five hundred fields. At the end of a week when the patient left hospital (with a supply of quinine tablets) the number of trophozoites was apparently the same.

Case 17.—Tamil. Weight, 105 lbs. Disease, benign tertian malaria. Peracrina was given for four days. Parasites were still present and the patient refused to continue the treatment.

Case 18.—Tamil. Weight, 100 lbs. Disease, mixed tertian malaria. Peracrina was given alone for five days. At the commencement of treatment there were twenty-five trophozoites in every hundred fields and at the end of five days their numbers were approximately the same. Peracrina was then discontinued and quinine was given instead, with the result that no parasites could be found after three days' treatment.

SUMMARY.

A supply of Peracrina 303 was received from the Haco Company who are the manufacturers. It is put up in pills weighing about 10 grains each. They consist of a mass of yeast cells and a little starch, stained with a yellow dye. The makers state that four hundred pills are required for the treatment of an ordinary case of malaria. The retail price of this quantity, in Singapore, is \$24, or two pounds sixteen shillings. Treatment with Peracrina is, therefore, much more costly than treatment with quinine. The optimum dose, according to the makers, is twelve pills a day, and they recommend that this dose should be continued for about three months. Few people will submit to this treatment.

The Haco Company state that the malaria parasites may increase during the first three weeks of treatment, and the temperature may rise occasionally. This makes Peracrina unsuitable for use in a country where malignant tertian infections are common and where death may ensue with shocking rapidity unless the number of parasites is rapidly reduced.

A report by Dr. J. Walker on the treatment of malaria with Peracrina, was sent to me by the makers; it was published originally in the *Archiv für Schiffs- und Tropen-Hygiene*. The examples of cures effected by Peracrina, were unconvincing, they did not prove that this substance had any effect on malaria parasites.

Eighteen patients who were suffering from malaria, in the District Hospital at Kuala Lumpur, were treated with Peracrina. Their average weight was 101 lbs., and they were given eight pills daily. Blood films were examined twice a day.

Nine of these patients were given Peracrina alone when they were first admitted to hospital; quinine was not given to them until its administration became imperative. The result was that, in all except one, the number of parasites either increased or remained stationary and it became necessary to give quinine.

The other nine cases were given quinine at the commencement of treatment, either alone or in

combination with Peracrina. As soon as the parasites had disappeared, quinine was discontinued and Peracrina was given alone. In two cases there was no relapse while Peracrina was being given, but they were under observation for only five and eight days, respectively. In the remaining seven cases the parasites multiplied when the quinine was stopped and Peracrina was powerless to prevent relapse.

CONCLUSIONS.

(1) Peracrina 303 consists of yeast cells, a little starch and a yellow dye.

(2) It is impracticable to administer Peracrina for a long period and in the large doses recommended by the makers.

(3) Peracrina is too expensive for general use.

(4) The clinical tests made in Kuala Lumpur did not show that Peracrina had any effect upon malaria parasites.

(5) Malaria parasites may increase during treatment with Peracrina and it is dangerous to employ it in place of quinine.

A Mirror of Hospital Practice.

STONE IN THE BLADDER FORMED AROUND A FOREIGN BODY.

By J. L. LUNHAM, M.B., F.R.C.S.I.,

LIEUTENANT-COLONEL, I.M.S.

Civil Surgeon, Dharwar.

A FEMALE patient was admitted into hospital on 9th May, 1925. She was an adult of about 35 years of age and of fairly good constitution. She had incontinence of urine and complained of pain behind the pubis and lower part of the hypogastric region. She could not walk on account of the pain. Her temperature on admission was 99.6°F.

On examination it was found that there was a stone of fairly big size in the bladder; it was adherent to its wall behind. There was a hard swelling in the front wall of the vagina; it was tender to the touch. There was tenderness and a little hardness just above the pubis.

On 11th May, 1925, she was put on the table and anaesthetised. Attempts were made to extract and crush the stone but without effect: the cavity of the bladder was found obliterated. An incision about 1½ in. long was made over the swelling in the vagina. The stone was seized with forceps and extracted; a stick came out along with it. The stone had formed at its thick end. The length of the stick was 5½ in.; the circumference of the stone at the head of the stick was 3½ in. The stick was lying with its

head in the bladder and its remaining portion in the walls of the vagina and uterus. The stone was phosphatic in nature. The wound was stitched with catgut sutures which were removed after ten days; the wound was then completely healed up. Pain and temperature had disappeared. The patient made an uneventful recovery and was discharged cured on 28th May,

inguinal glands were more markedly enlarged on the left than on the right side. The patient looked emaciated but had no defect in any other organ.

TREATMENT.

Operation.—As soon as the patient gained a little strength after a course of free and liberal

25. At the time of her going, she had complete control over the bladder and its cavity had formed.

On asking her as to how she came by the stick, she said that she had inserted it there about two years ago to bring about abortion. Abortion was caused but she could not take out the stick, so it had remained there for about two years.

AMPUTATION OF THE PENIS.

By S. C. DAS GUPTA, L.M.S. (Cal.),

Senior Surgeon, Bir Hospital, Katmandu, Nepal.

SURYAMAN, a Hindu Newar, aged 48, was admitted into hospital on July 16th, 1924. About 17 months previously the patient had noticed a small fungiform growth on the prepuce; he had had phimosis since childhood, but gave no history of any venereal disease.

Condition on admission.—The organ had exactly a cauliflower-like appearance from near the tip to the root (*vide* photograph; removed organ shown suspended by a piece of thread); the

diet, I put him up for operation. Under chloroform, the patient lying on his back, I removed the enlarged glands of the inguinal region on both sides in the first place and stitched up the wound, leaving a small gauze drainage at the outer aspect. He was then placed in the lithotomy position and an elliptical incision was made around the root of the penis joining both above and below, which was prolonged downwards precisely along the median raphe up to the lower angle of the pubic arch. Next, the line of incision over the raphe having been deepened and the testis on each side retracted, the body of the penis was laid bare.

Dissection of the Urethra.—As the part was foul-smelling and full of septic discharge, I did not pass the sound per meatus for fear of carrying the infection deep down. I dissected out the corpus spongiosum and lifted it up on the aneurism needle (just as is done in an intravenous injection) and divided it about the middle and picked up the end with a Kocher's forceps. Then I passed a rather tight-fitting sound up to the membranous portion of the urethra to keep the same as a guide. Next, I proceeded with

separating the remainder of the urethra, having a grip on the sound, from the corpus cavernosum quite back to the triangular ligament, care being taken not to puncture the urethra; then I removed the catheter.

Removal of the corpus cavernosum.—The diseased portion of the penis having been wrapped up in a sterilised gauze and held up by means of a tissue-forceps, dissection was carried downwards separating the corpus cavernosum from the surrounding structures, the suspensory ligament being divided and the accelerator urinæ slit open up to the crura. Meanwhile, the dorsal arteries and vein divided in the course of operation were secured. Next the crura were dissected and ultimately detached by scraping out from the rami of the os pubis by means of a periosteal elevator. Leaving about half an inch of urethra the remainder was snipped off; and lastly, the severed end was slit up longitudinally and the edges were stitched with the margins of the skin at the lowermost portion on either side, about $\frac{1}{4}$ inch protruding and everted. A small drainage tube was left inserted at the lower margin of the wound, about an inch above the insertion of the newly formed urethra, and a soft rubber catheter was left in the bladder attached to a rubber tube for continual drainage into a 4-lb. wide-mouth bottle into which some carbolic lotion was poured to keep the end of the tubing always dipping in. A double spica (bandage) of the groin was applied covering the inguinal region and scrotum up to the opening of the new meatus.

After-treatment.—The patient was kept in Fowler's position for 10 days to ensure free drainage from the bladder. The gauze drainage and tubes were removed after 48 hours. The catheter was withdrawn on the 8th day when the stitches were taken out. The wound healed up by first intention everywhere except at the upper part, near the root of the penis; this also healed up after 15 days.

Note.—In this case I did not remove the testes, which were not in the least affected. Cancer of the penis is very prevalent here; I have operated on over half a dozen such cases and have removed the testes in only two.

In my former cases I did not drain the bladder continuously by a catheter, and these cases getting septic and the dressings being usually soaked due to contamination with urine, I have discarded this practice and now retain the catheter continuously, held up in position by a sticking plaster, till the stitches are removed.

As regards the urethra, I have come to the conclusion that it is best to transplant it as low down as possible with its end directed downwards. The level of the urethra, at which it should be sutured, must be at the junction of its two curves (concave and convex—from above downwards) which meet at about a point midway between the triangular ligament and the bulb.

Nearly half of my cases had strictures of the urethra; the present case came back after three months with a very narrow opening, not admitting even the point of a fine probe. I had to dilate the urethra and keep him in hospital for two weeks more. I saw him last about two months ago; he has no trouble now.

In one of my cases I had again to dissect out the urethra under chloroform and stitch up the everted edges in the manner described above. I believe if the end of the urethra be kept properly everted and a strict aseptic condition is preserved throughout, stricture is not likely.

In conclusion, I think, it is better for a beginner to use a silver catheter in place of a sound, because the former will not only be of help in the dissection of the urethra but will also afford an unmistakable proof of its passage into the bladder by the jet of urine through its opening.

(N.B.—The photo was taken three months after the primary operation. The catheter is seen passed into the bladder and the stillete through the severed end of the urethra.)

SOME SURGICAL CASES.

By RAI SAHIB MUKAND LAL, L.M.S.,
House Surgeon, Civil (Dufferin) Hospital, Delhi.

Case 1.—Pirbhu, son of Nem Sukh, aged 16 years, Hindu male, received a gunshot wound of the abdomen on 15th July, 1924. The shot entered just above the left iliac crest and lodged somewhere on the anterior surface of the sacrum. The boy showed no signs of peritonitis and the superficial wound being healed, he was removed from the hospital by his parents on the 17th but was re-admitted on 25th July, 1924, at 9 P.M. with symptoms of acute obstruction. He was operated on immediately—a tag of omentum was found adherent to the parietes near the wound of entrance forming a loop through which the gut had passed and thus caused obstruction. The band was divided and the gut, being in good condition, replaced. Two wounds were observed in the gut, each closed by a small slough. The two points were invaginated and closed by purse-string sutures. No search was made for the shot as the patient was in a very critical condition and the abdomen was closed quickly. Recovery was uneventful and the patient was discharged cured on 22nd August, 1924.

Case 2.—Durbari, son of Ramjas, aged 12 years, Hindu male, admitted on 10th August, 1924, with symptoms of pain in the abdomen and fracture of the right clavicle. He said that one day before this a heavy bale of cloth fell upon him and gave rise to the trouble. The abdomen was a little rigid; temperature 100°F. pulse quick; and slight pain and difficulty in

passing urine. He was put to bed—the urine drawn off with a soft catheter and the bowels relieved with enemata. On 12th August, 1924, the rigidity and swelling of the abdomen had increased; pulse was small and thready; temperature 100.4° and very little urine could be drawn off by the catheter. Laparotomy was done, a medial incision being made below the umbilicus. The main abdominal cavity was found to be well shut off by adhesions. There was a collection of pus in the pelvis and on inspection a rupture of the bladder was discovered. Good drainage was provided and the wound left open. Recovery was steady and gradual and the patient was discharged cured on 5th October, 1924, the wound closed and healed up as in a case of suprapubic cystotomy.

Case 3.—Harpiary, wife of Surajpal, aged 35 years, Hindu female, came in with a big tumour in the abdomen of about 3 years' duration. She said it was gradually increasing in size and giving rise to pain and discomfort. The growth felt like a solid tumor, non-adherent and freely movable. On examination per vaginam the uterus was found free and the right adnexa thickened. Menstruation was occurring at usual periods but the flow was less than normal. Laparotomy was done on 17th September, 1924, with medial incision below the umbilicus. A dermoid cyst of the right ovary was found which was removed, the pedicle ligatured and sutured after invaginating the stump. A true floating right kidney was found which was lying high up in the pelvis. The left kidney was cystic. It was thought sound to leave the kidneys alone. The patient was discharged in good health on 3rd October, 1924.

Case 4.—Yadu, son of Gurdial, aged 28 years, Chamar male, admitted on 3rd October, 1924, with symptoms of acute obstruction of six days' duration. Laparotomy was done at once. Two bands of mesentery were found which caused the obstruction; these were cut and ligatured and the gut relieved; wound closed as usual and the patient discharged cured on 14th October, 1924. No complications occurred.

Case 5.—Moola, son of Nathu, 35 years, Brahman male, admitted on 30th August, 1924, with a history of injury due to the passing of a cart wheel over the left side of his chest where it produced an ecchymosis about 4 inches by $\frac{1}{2}$ inch. Duration about 12 hours. He had difficulty in breathing—vomiting—and the urine was slightly blood-tinged. On 1st September, 1924, distention of the abdomen increased but there were no definite signs of obstruction. Laparotomy was done. First a medial incision was made and about a pint of blood evacuated from the peritoneal cavity. As the collection seemed mostly in the left flank, the first incision was closed and another made in the anterior axillary line from where more blood was evacuated. The spleen was searched for rupture and, although enlarged, no tear was discovered. The

condition of the patient being serious the wound was rapidly closed without making any further search for a rupture or a tear. Both wounds healed by first intention. The patient being very weak, recovery was gradual and slow; no further accumulation of blood could be detected. There were three complications noticeable:—

1. A patch of pneumonia on the left side probably due to trauma.

2. Bleeding from the bladder which was profuse and lasted for a week—most probably due to primary injury of the bladder itself.

3. Bedsore; this was unfortunate but understandable considering the low vitality and extreme weakness of the patient after so much loss of blood.

Case 6.—Kundan, son of Hukma, 35 years, Hindu male, admitted on 9th October, 1924, in extremely weak and emaciated condition; constant pain in the abdomen which presented an enlarged spleen and two fairly big masses resembling enlarged glands in the epigastric region. The masses were slightly mobile and appeared attached to the posterior wall—non-adherent to the parietes; slight rise in evening temperature to about 99°F; duration 6 years. Considering the general condition of the patient and the size of the masses a provisional diagnosis of tubercular mesenteric glands was formed and surgical interference was thought inadvisable. The patient, due to constant pain, pressed for an operation; and a few days' rest and nourishment helped him to pick up a bit in health. Laparotomy was done on 17th October, 1924; a pararectal incision being made on the site of the tumour. The growth was found to be in the mesentery and fixed to the posterior wall. A small incision was made into the growth, and typical dermoid cyst contents came out. Removal being impossible, the peritoneal cavity was shut off and a drainage tube inserted after removing as much of the cyst contents as possible. This relieved the patient of his pain and discomfort and the cavity went on emptying itself without any further abdominal complication. Sometime later infection took place and the patient died ultimately of exhaustion.

CASES OF APPENDICULAR ABSCESS.

Fifteen cases of appendicular abscess have been treated since April, 1924. The ages of patients varied from 8 years to 50 years and the duration of illness from 4 to 30 days and in one case even longer than this. Thirteen cases were cured and one died due to intense toxæmia. Fæcal fistula formed in 13 cases after operation which closed up in about a week's time.

Experience shows that appendicitis is a much more common disease than it is thought to be among the Indians but it is a pity that most of the cases go undiagnosed or are delayed to such an extent as to form an abscess. Operation is resorted to only as a last measure.

Appendicitis duration.	Age.	Result.
4 months	40 years	Died.
25 days	20 "	Cured.
15 "	35 "	"
15 "	26 "	"
Chronic	50 "	"
30 days	40 "	"
30 "	35 "	"
30 "	20 "	"
7 "	8 "	"
6 "	22 "	"
14 "	15 "	"
6 "	20 "	"
5 "	30 "	"
8 "	30 "	"
3 months	40 "	"

N.B.—A few points about these cases are:—

1. Chloroform was used as general anaesthesia.

2. Picric acid 3 per cent. solution in rectified spirit as an antiseptic for the skin has proved a very reliable agent.

3. Silk has been used for all sorts of sutures except the skin. Its sterilization is easy but requires a little care. Boil the hank for 15 minutes, store up in mercury lotion 1-1000 and boil again for half an hour before operation.

4. There have been no complications and little or no reaction after the operation.

OBSERVATIONS ON A FATAL CASE OF LIVER ABSCESS.

By J. P. ARLAND,

LIEUTENANT, I.M.S. (T.C.),

Royal Air Force Combined Hospital, Busrah.

MOHAMMAD KHAN, a bearer in the service of the 1/2 Bombay Pioneers, was admitted into the Cantonment Hospital, Kirkee suffering from a large and painful prominence in the right hypochondriac region.

Previous History.—The patient was addicted to alcohol for the last ten years. He contracted dysentery twice. He served in Mesopotamia for two years.

Condition on Admission.—The patient was thin, weak and wasted; the skin dry, wrinkled and atrophic; and the conjunctivæ were bile-tinged. There was dyspnoea on slight exertion. He complained of increasing debility and loss of flesh and a dull ache in the liver area at times radiating to the right shoulder. An appreciable protuberance the size of a large apple was seen immediately below the right costal arch; the skin over the tumour was oedematous and shiny.

Diagnosis.—A provisional diagnosis of liver abscess was made and was confirmed by aspiration.

Operation.—The patient was prepared for operation. A preliminary intravenous injection of 2 pints of saline with adrenalin was made. An incision 2 inches long was made over the most salient part of the tumour; after division of the superficial structures the anterior sheath of the rectus was incised, the muscle displaced internally and the peritoneal cavity opened up. A large rounded liver mass presented in the wound. The peritoneum was packed all round with

two tiers of gauze towels and an incision $\frac{1}{4}$ inch long was made in the bulging abscess. There was a sudden gush of pus which rose to a height of about 10 inches. It was noted that the wound in the abscess had increased to 1 inch; this was doubtless due to the friability of the cellular tissue combined with the great internal tension of the abscess cavity. Pressure was instantly made over the opening in order to provide for a slow and uniform flow.

At this stage the patient stopped breathing; his head was instantly lowered and artificial respiration commenced. After a lapse of 10 minutes, when no signs of recovery were perceptible, a rapid incision was made in the fourth left inter-space and the heart exposed. Cardiac massage was started and ten minims of adrenalin hydrochloride injected into the cardiac muscle; instantly the heart began to beat. Artificial respiration was all the while kept on but to no avail; the heart continued to beat for 10 minutes and ceased in diastole.

POST-MORTEM.

(1) The liver was found destroyed to the extent of 2/3rds of the whole.

(2) Heart and lungs empty of blood.

(3) Intestines deeply congested.

(4) The liver was in the greater part of its extent represented by a thin capsule enclosing cellular debris.

OBSERVATIONS.

(1) The quantity of pus evacuated was extraordinary, amounting to a little over two pints.

(2) Death was due to cardiac and respiratory failure.

(3) A marked feature of the case was the early onset of intravascular thrombosis throughout the body.

(4) The emptiness of the heart and lungs may be explained by the great suction action exercised by the inferior vena cava when it was relieved of the great pressure of the abscess pressing upon it.

It may be inferred from the conditions observed in this case that—

(5) Stitching the liver to the abdominal wall in order to shut off the peritoneal cavity is not a safe procedure in cases where the abscess is large and the glandular tissue friable.

(6) In the process of aspiration that part of the needle traversing the abdominal wall is for practical purposes a fixed point, while the part in the friable liver and abscess cavity is not so fixed as one would imagine.

(7) Destruction of the major portion of the liver is not incompatible with life.

Holding these facts in mind, consider the effect on the liver occasioned by the respiratory movements.

The liver moves up and down during respiration; this motion causes the mobile portion of the needle to tear through the liver and thus favours peritoneal extravasation.

In conclusion, I have to thank Captain S. G. Chavan, I.M.S. (T.C.) for his valuable assistance during the operation.

A CASE OF ACCIDENTAL ABDOMINAL INJURY.

By K. V. JOGLEKAR, M.B., B.S.,
Ranebennur.

ON 4th April, 1925, at 3 P.M. I was called up to see a woman, aged 55, with an abdominal injury caused by the horn of a bullock; the accident had occurred in the early morning. I reached the place in the evening at 6 P.M. and found the woman in good condition (pulse and temperature normal). I found that the intestines had come out through the crescentic tear and were wrapped in a piece of dirty cloth. I wanted to stitch the wound under general anæsthesia but the woman declined, saying that she wouldn't trouble me at all even if I did it without anæsthesia.

After removing the cloth I found nearly 9 or 10 feet of the gut out through the wound which was $2\frac{1}{2}$ inches in length. Fortunately the gut was not at all injured. I washed the gut with warm saline and having thoroughly cleansed it pushed the gut in and stitched the wound. Afterwards I gave 3 drachms of brandy. After the operation for 24 hours or so the woman was restless but then made a rapid recovery and after 12 days I found the wound completely healed. Two months later I found the woman in sound health.

The special features of the case being the non-injury of the gut and the rapid recovery even after the gut had been kept in a dirty cloth for fully 12 hours.

*A CASE OF HYDATID CYST OF THE RIGHT PAROTID AND SUBMAXILLARY GLANDS.

By N. P. SHRIVASTAVA, I.M. & S., M.B., B.S.,
Officiating Civil Surgeon, Seoni.

A YOUNG man of about 24 years of age was admitted into the Seoni Main Hospital on 21st March, 1925, with a tumour about the size of a cocoanut situated in the right parotid and submaxillary regions. On palpation the tumour felt loculated and each loculus gave a fluctuating feeling. The differential diagnosis apparently rested between the following:—

- (1) Lipoma.
- (2) Cystic degeneration of endothelioma of the parotid.
- (3) Retention cyst of the parotid or submaxillary gland.
- (4) Cystic hygroma of the neck.

Lipoma was eliminated by:—(a) The site of the tumour being an extremely rare seat of lipoma.

* Read at the Annual Conference of the C. P. Branch of the Indian Provincial Medical Science Association, Nagpur.

(b) The characteristic lobulation of the tumour mass in a lipoma being absent.

Cystic hygroma was eliminated by:—(a) The tumour involving the parotid region essentially, as evidenced by the lobe of the right ear being enveloped and the anterior surface of the masseter being occupied by the tumour. Cystic hygroma is mostly confined to the neck, being caused by dilation of lymph spaces of the branchial clefts.

(b) Cystic hygroma is usually congenital; the tumour in question started during the childhood of the patient and steadily progressed in size till it assumed the present dimensions in the course of about 20 years.

It could not be decided whether the cyst was a hydatid, retention or degeneration cyst.

The patient was operated upon on 25th March, 1925. A curved incision over the prominent part of the tumour was made and as soon as the fascial and muscular strata were cut through, the cyst wall at its thinnest part was accidentally punctured and there popped out a globular ball characteristic of a hydatid. The cyst wall had contracted numerous adhesions and threw prolongations under the sternomastoid in close proximity to the carotid sheath, substance of the parotid and submaxillary glands, stylomastoid space and under the angle of the lower jaw. Careful dissection, taking special care of the branches of the facial nerve, radicals of the carotid sheath, hypoglossal nerve and its branches, internal maxillary artery, auriculo-temporal nerve and ducts of the parotid and submaxillary glands, had to be gone through to remove the cyst wall in its entirety. Punctures and extension of the daughter cysts could not be avoided owing to the complex adhesions and thinness of the ectocyst. The wound was well irrigated with normal saline solution to wash out the hooklets of the worm discharged with the cystic fluid. Drainage was provided at the most dependent part of the wound.

The patient made an uneventful recovery. Partial paresis of the affected side of the face was noticed but this was mending itself steadily, when the patient was discharged cured on 5th April, 1925. Neither rash nor toxæmic phenomena showed themselves, though their possibility was anticipated owing to the rupture of the cyst wall and contamination of the wound.

The case is mentioned not because it illuminates any new or special surgical technique but because the site of the tumour is a very rare seat of hydatid, and text-books on surgery are mostly silent on the situation.

The patient was a Gond—a class which rears dogs for hare shooting etc., and the presumption is that water or uncooked vegetables contaminated by dogs' excreta were taken and the ova of the hydatid were sucked in through the Wharton's and Stenson's ducts and proved prolific of the cyst.

Indian Medical Gazette.

NOVEMBER.

TREATMENT OF KALA-AZAR.

TEN years ago, there was no specific treatment for kala-azar. The patient who became infected with the disease had to look forward to a long-continued illness which would probably terminate at his death. There was just a chance that the disease might disappear spontaneously or that some severe secondary infection, such as pneumonia, would raise his general resistance—his leucocyte count in particular—and thereby help him to get the better of the Leishmania infection. Numerous forms of treatment were tried, most of these being directed towards the production of a leucocytosis, but there was little evidence that any of them increased the patient's chance of survival to any extent. The introduction of the tartar emetic treatment revolutionized the whole outlook of the kala-azar patient. Sir Leonard Rogers was the pioneer of this treatment as far as India was concerned; a number of cases of Indians and Europeans were treated under his directions in the Medical College and in the Presidency General Hospitals in Calcutta. About the same time Muir started to treat large numbers of cases as out-patients at Kulna and laid the foundations of the system of wholesale treatment of the disease. The provision of hospital accommodation for even a tenth of the cases of kala-azar in Bengal and Assam, would have been a totally impossible task, but the treatment as out-patients of the hundreds of thousands of patients that modern diagnostic methods have shown to be suffering from the disease is by no means an unattainable ideal. Distinct progress towards the solution of the problem of the treatment of the disease was made during the next few years; the advance consisted of the introduction of sodium antimony tartrate, as an alternative to the potassium salt, in the production of pure preparations of the tartrates, but most of all in the education of the medical profession in the methods of treatment with these compounds. The problem was tackled vigorously in Assam where Lieutenant-Colonel T. C. McCombie Young, I.M.S., the Director of Public Health, organised large numbers of treatment centres all over the province and later in Bengal where the authorities had been slower to realise the gravity of the situation which was to a certain extent overshadowed by the malaria problem. The dispensary returns in the two provinces showing the number of cases of kala-azar treated each year since 1920 are as follows:—

	Assam.	Bengal.
1920	7,188	7,382
1921	15,880	7,689
1922	19,659	13,317
1923	35,071	57,238
1924	48,770	139,085

Up to the year 1922 little improvement had been effected in the treatment of the individual case. An organic compound of antimony, "Stibenyl," had been introduced and used with success in England and on the continent, but in India the preparation proved a failure. The first pentavalent organic compound that was used with any degree of success was urea stibamine; at first the results were irregular but it was soon apparent that on the whole the results obtained with this compound were infinitely better than those obtained with the simpler antimony salts.

About the same time "von Heyden 471," another pentavalent compound very similar to "Stibenyl," was introduced. Good results were obtained with this compound which had the advantage of being absolutely stable in the Indian climate. A few other pentavalent compounds have been used and found to have a curative value similar to the above mentioned compounds, but these have not yet come into general use. The advantages of the pentavalent compounds over the tartrates may be classified as follows:—

(i) The compounds are much less toxic and can, therefore, be administered in larger doses.
(ii) The total amount of antimony which is necessary to effect a cure can thus be administered in a much smaller number of doses. About 12 doses of the pentavalent compounds—against the 30 doses of sodium antimony tartrate—can be looked upon as the average number necessary for a non-resistant case.

(iii) Resistant cases, which show little improvement with the tartrates, rapidly improve when given the relatively larger doses of antimony in the form of the non-toxic pentavalent compounds.

(iv) Certain disagreeable symptoms, such as coughing and severe joint pains, which are frequently associated with the sodium antimony tartrate treatment, do not occur when the pentavalent compounds are injected.

Against the pentavalent compounds there is only one point, that is *cost*. Whereas the best preparation of sodium antimony tartrate costs about 1 anna a gramme, urea stibamine costs Rs. 12-8 to Rs. 25 per gramme, according to the size of the ampoule purchased, and "Stibosan" (the proprietary name for "von Heyden 471") Rs. 10 per gramme. That is to say, the cost of the pentavalent compounds is at least 160 times as great as that of the antimony tartrates. This means that to effect a single cure (to ensure which takes on an average 3 grammes and not one gramme which amount will only effect a small percentage of cures) the cost will be 3 annas, Rs. 40 (about) or Rs. 30 according to

whether sodium antimony tartrate, urea stibamine, or Stibosan are used.

Let us consider the facts for and against the pentavalent compound in the reverse order of their importance. The symptoms associated with the injection of the antimony tartrates enumerated above are the exception rather than the rule and seldom cause more than slight inconvenience to the patient. (No mention has been made of pneumonia as a complication of antimony tartrate injections because it is a complication which often occurs in the untreated case. It is, however, a complication which turns up with such regularity—in about 5 per cent. of hospital cases treated with sodium antimony tartrate—that it is impossible not to associate it with the known fact that some of the antimony in sodium antimony tartrate, which forms an acid solution, is precipitated when the latter comes in contact with the alkaline blood and that this precipitate will probably be caught in the lung capillaries. Fairly extensive experience with Stibosan has shown that with this compound, at any rate, pneumonia is a very much less common complication).

It is obvious that the pentavalent compounds are indicated where the patient has any of the unpleasant symptoms associated with injections of antimony tartrate and in cases which have any lung complications. Next, it is perfectly obvious that all cases which are resistant to treatment with the tartrates should be given one of the pentavalent compounds. Finally, there is the question of the reduction in the length of the course of treatment on the one side and the high cost of the drug on the other. These points will have to be considered in relation to the different classes of patient,—the private patient, the hospital patient, and the outdoor dispensary patient.

The problem of the private patient is a simple one; by expending the larger sum, Rs. 40 or Rs. 30, he will require only 12 instead of 30 injections and will thereby save 18 visits from his attending physician. Even if he is only paying Rs. 5 per visit the balance will be greatly in his favour.

The next case is that of the hospital patient; here the choice of treatment lies with the hospital authorities and it is their point of view that must be considered. Urea stibamine is being supplied to certain hospitals and public bodies at a very much cheaper rate than that charged to the general public, Rs. 3-6 per gramme is the figure which is quoted by the Director of Public Health, Assam. Stibosan is also supplied in bulk for hospital use at a very much reduced rate. The average cost of treating one case, therefore, works out at Rs. 10-2 or about Rs. 10 more than the cost of sodium antimony tartrate. The length of time which each patient has to stay in hospital is reduced from 10 to 4 weeks (allowing 3 injections each week) so that there will be a saving of 6 weeks of hospital diet and accommodation; this easily compensates for the extra cost of the

drug and the actual cost of treating each patient is thus reduced. The source of revenue of the hospitals does not, however, vary directly with the number of patients treated so that there is another point of view to be considered. In most places in Bengal the supply of kala-azar patients is inexhaustible so that empty beds are rapidly filled and the hospital authorities are faced with the fact that every bed available for the treatment of kala-azar patients is filled and emptied 12 times during the year, if the pentavalent compounds are used, instead of 5 times as in previous years, and that the cost of maintaining specific treatment will be Rs. 121-8 instead of As. 15 per annum for each bed available. Looking at the matter from both points of view, it is obvious that the balance is in favour of the pentavalent compounds and that in time these will have to be used almost exclusively in hospitals; if the extra expenditure cannot be covered then the number of beds available for kala-azar cases will have to be reduced, the other beds being made available for patients suffering from less expensive diseases.

Finally, there is the case of the dispensary patient. During the last few years societies have been formed in Calcutta and elsewhere whose main object has been to give free treatment for kala-azar to villagers who can neither afford to pay a private doctor nor even their railway fare to, and their maintenance in, Calcutta whilst they undergo treatment. The injections have usually been given by voluntary workers, so the working costs of these societies in proportion to the useful work they have done has been very low. The cost of the sodium antimony tartrate required to treat, say, 1,000 cases would be less than Rs. 200, a negligible sum, but if a pentavalent compound were used, at the cheapest rate, it would mean an expenditure of Rs. 10,000, a very considerable sum to such a society. Or take the case of the Assam Government during 1924. 48,770 cases were treated at the dispensaries in the province; these were for the most part treated with sodium antimony tartrate. The extra expenditure entailed in substituting, say, urea stibamine, would have been nearly Rs. 5 lakhs.

Let us consider what will have been gained by this extra expenditure. The final result to the average patient—we will for a moment not consider resistant cases—will be the same, the recovery rate being about 90 per cent. in either case. The patients will have been saved 18 visits to the treatment centre. In the case of the women and children, this will not entail much, if any, financial gain; in the case of a man it will probably mean the saving of 18 days' work. In addition, if the man is so ill that he cannot work, his return to comparatively good health will be more rapid—at a general estimate he will have saved another 12 days or a total of about one month.

A reduction in the number of injections given would have reduced the cost of maintenance in

Nov., 1925.]

the matter of syringes, etc. A slight saving in staff would also be effected but this would not be in proportion to the number of injections given as in many smaller places the full staff would have to be maintained.

Of the patients attending a dispensary only a certain percentage take a full course of injections, the majority decide when they have had, say, 20 injections and are free from fever that they are cured and do not return for the remaining 10 injections. Some of these patients remain cured but a proportion relapse and then have to have another complete course of injections. This is undesirable from many points of view and one cannot help thinking that this falling off would not occur so frequently if the full course of injections was only 12 instead of 30.

Another point that will have to be considered is the fact that at the present time the pentavalent compounds of antimony are a very valuable commodity. It is fairly well known that all the quinine which is paid for by the Government for hospitals and dispensaries does not reach the patients for whom it is meant. Urea stibamine is retailed at Rs. 12-8 (or more) per gramme, that is to say, its value is about 7 times that of gold—its expenditure would, therefore, have to be checked very carefully.

On the whole we feel that the time has not yet come for public bodies to expend the very large sums that would be necessary to make treatment with pentavalent compounds of antimony the routine treatment in dispensaries, but at the same time it seems desirable that some arrangement should be made for the treatment of cases in which the pentavalent compounds are especially indicated, for example, in resistant cases.

It is obvious that the only real obstacle to the introduction of the new antimony compounds into general use is the present very high cost. There are two factors which influence this price—firstly, the process of manufacture is an expensive one and, secondly, there has, up to the present, been little competition in the manufacture of these compounds. It is not suggested that manufacturers have been profiteering but it is obvious that if a number of commercial firms can produce pentavalent antimony compounds of proved leishmanicidal value, healthy competition will be started and the various manufacturers will be compelled to study economy in the process of manufacture. There is, of course, the danger that useless and even dangerous antimony compounds will be produced and sold at a cheap rate by unscrupulous persons, either as one of the compounds whose value has been proved or as "an improvement" on one of these compounds.

It seems, therefore, desirable that in order to combat any attempt at "cornering" any of these compounds reputable chemical manufacturing firms should receive every encouragement to manufacture and place on the market any pentavalent compound that has been thoroughly tried and shown to be of definite therapeutic value in

the treatment of kala-azar but that at the same time the public, and more especially the medical profession, should be warned against using any preparations that have not had a very thorough clinical trial by a disinterested observer at some well-recognised institution.

L. E. NAPIER.

Current Topics.

Arthritis in Childhood.

By F. JOHN POYNTON, M.D., F.R.C.P. (Lond.),
Lancet, April 18, 1925.

WE give some extracts from the report of this important lecture.

Apart from tuberculosis, a severe arthritis is comparatively infrequent in children. In adult rheumatoid arthritis we often fail to detect any convincing evidence of a local focus.

In childhood, with few exceptions we can clearly trace the factor of infection, tuberculous, rheumatic, syphilitic and gonococcal arthritis, influenzal, pneumococcal, meningococcal, and typhoid arthritis, and the septic staphylococcal and streptococcal forms. There are, nevertheless, as in the adult some mysterious cases, variously termed Still's disease or rheumatoid arthritis and some remarkable examples of osteo-arthritis. But we cannot but feel, when we consider the cases of Still's disease, that they must also be infective in origin when we recall the fever, the enlarged glands and spleen, the sweating, and general toxæmia.

Almost every example is an instance of one manifestation of a general disease and if we can hope to solve such a problem as the pathology of arthritis it must be from a study of all the other manifestations of these causal diseases, any one of which may throw a sidelight on the difficulties of the particular symptom "arthritis."

Tuberculous Arthritis.

Poncet, in 1897, described a "tuberculous rheumatism" meaning by this an arthritis which closely resembled in its feature rheumatoid arthritis. That acute tuberculous polyarthritis may occur in children is certain, and you may easily mistake it for acute rheumatism.

Still's Disease.

The chief characteristics are:—(1) An onset which is almost always before the second dentition. (2) The female sex is more often affected than the male. (3) The cause is unknown, one factor of which is that several of the cases have come from low-lying and damp situations. (4) The articulations, apart from the thickened and vascular synovial membranes and ligaments, show little change. In some long-standing cases the synovial membrane has eroded small pits in the periphery of the cartilages, and there may be some fibrous adhesions, but there are no osteophytes, and there is no eburnation of the bones. (5) The lymphatic glands and spleen, which are enlarged, show little change in structure, though there may be small hæmorrhages.

As a rule the onset of the disease is gradual, with stiffness of some of the joints as an early symptom. The knees, the wrists, and the cervical spine are first affected, and the changes involve the capsules of the joints and not the bones; and there is but little fluid exudation and that viscous and clear. The hands and feet are soon implicated, and the ankles and feet may also soon be attacked. The child has outbursts of pain such as occur in the rheumatoid arthritis of adults. This disease is polyarticular and remarkably symmetrical in its distribution, with great tendency to early contractures and rigidity. The lymphatic glands

are enlarged in association with the joints that are affected; they are not, as a rule, tender and never suppurate, but they may reach a considerable size. The spleen may extend one or two inches below the costal arch but, as it tends to shrink again in the quiescent stage, this enlargement must be sought for during the more acute phase. Valvular lesions are not found, but in a few cases a film-like pericarditis and pleurisy have been discovered after death. There may be some exophthalmos and occasionally jaundice, and the temperature in severe cases is high and swinging between 100° and 104° F., and then the child may have severe sweatings and be extremely ill.

The arthritic exudations, the blood, and in some cases the lymphatic glands, have been removed during life. The results have either been negative or, if micrococci had been isolated, they have not been demonstrated, or reproduced the disease.

Osteo-Arthritis.

Osteo-arthritis in childhood—a chronic arthritis with hypertrophic changes in the synovial membranes, ulceration of the cartilages and osteophytic formation leading to bony thickenings and out-growth—is a very rare occurrence, and, though of much interest, a subject upon which it is difficult to obtain information.

Pneumococcal Arthritis.

This is a very rare event. As a rule one joint is attacked and the order of frequency is the knee, the shoulder, the hip, the wrist, the ankle, the elbow, and the sterno-clavicular joint. The proportion of suppurative to serious cases is about 10 to 1.

Some interesting details were given on the bacteriology of arthritis, by Dr. Nabarro from the Research Department of the Hospital for Sick Children. They are concerned with the result of the examination of the exudations obtained from the joints of 108 cases of arthritis between 1917 and 1924.

In 54 of these the tubercle bacillus was found, or the case on clinical and cytological grounds was most probably tuberculous. Fifty-four were non-tuberculous.

In 21, streptococci were isolated and grown.

In 11, staphylococci were isolated and grown.

In 11, the exudation was sterile.

In 5, the pneumococcus was isolated and grown.

In 3, the influenza bacillus was isolated and grown.

In 1, staphylococci and streptococci were isolated and grown.

In 1, the *Staphylococcus albus* and *citreus* were found. In 1, a Gram-negative bacillus (unidentified) was found.

More than half of the non-tuberculous cases, were under 2 years of age. Eleven were streptococcal and five staphylococcal, three pneumococcal, three influenzal, two were sterile, and one was possibly gonococcal, but the report was doubtful. It is interesting to find that there was not a single case of meningococcal arthritis.

Gonococcal arthritis is a very rare experience, only one doubtful case is recorded by Dr. Nabarro. Congenital syphilis frequently affects the bones and cartilages and may also cause arthritis.

The best defined cases are those in which both knee-joints are attacked and show large, puffy, almost painless swellings which fail to react to any treatment until the true cause is discovered. The diagnosis from tuberculous arthritis may be difficult, but the other stigmata of the disease and the blood reaction usually give the key to the solution.

Influenzal Arthritis.

In October 1924, Dr. Nabarro and Mr. J. F. H. Stallman published a record of three cases of influenzal arthritis occurring in infancy. To those who are interested in the arthritis of adult life these exact records must be valuable, for they will recall how often in cases of rheumatoid arthritis a serious advance in the disease may follow an attack of severe influenza. Here we have proof that the influenzal infection itself may attack the

joints of children. In these three infants the arthritis affected in each case the knee-joint. The exudations were purulent and the Gram-negative bacilli were present in numbers and were both extra and intra-cellular. Two of the cases recovered and the final results were good. One died of influenzal meningitis, but the arthritis in this case also was running a favourable course. The writers, however, point out that in some of the recorded cases there has been total disorganisation of the joints affected. The treatment of these three cases was surgical.

Arthritis and Mumps.

Dr. P. Maisondieu calculates the frequency of its occurrence at just under 0.5 per cent. It is usually a late manifestation commencing about fourteen days after the disappearance of the parotitis, and it may synchronise with an attack of orchitis. The distribution is as a rule monarticular, thence spreading sometimes from one joint to another. There may be much pain and swelling, or again there may be pain in several joints but no swelling. Suppuration is the exception. The temperature may be slightly raised and the duration of a prolonged attack extend over five or six weeks.

Hæmophilic Arthritis.

Hæmophilic arthritis is very uncommon. One of the most obvious features is the acute onset with intense pain; another is the remarkable recovery that may occur in the joints, which again and again seem as it were to rebound from the sudden injury to their structure. Nevertheless we find that there will eventually arise an increasing disability, at first from stiffness, later from more serious damage of the type of an osteo-arthritis. The knees are the joints most often attacked and eventually severe crippling and ankylosis result.

As a rule the diagnosis is not difficult, for we have so frequently a previous history of bleeding either in the patient or in his forbears, and the intense rapidity of the onset, the pain, and the discoloration of the skin round the joint usually also guide us aright.

Dr. Lovell Gulland has found fresh serum most useful. Horse serum may be used either by the mouth or intravenously in 10 c.cm. doses.

Treatment.

The treatment of arthritis in childhood rarely presents any special features from the medical aspect. Rheumatic arthritis is frequent, but with rest the rapid subsidence is remarkable, and we all know the value of the salicylate compounds for this symptom.

The problem in Still's disease is far different. Every sort of drug and treatment has been tried, but no one can claim any certain remedy. Septic foci should receive treatment, but there has been no convincing evidence that as a result the disease has relented. It is important that the patients should be rescued from damp and cold surroundings.

Some Observations on the Routine Treatment of Syphilis.

By L. W. HARRISON,

Practitioner, June, 1925, p. 400.

COLONEL L. W. HARRISON recommends the adoption of certain principles.

(1) Not to risk a relapse, since the eventual eradication of the disease seems then to become much more difficult.

(2) There is no test by which the moment at which the spirochæte of syphilis dies can be determined. We know that all tests of the serum and spinal fluid may give negative results for as long as two years or more and then become positive.

(3) The effect of treatment is not the same in different cases of syphilis, though these may be in the same stage and present the same outward manifestations of the disease.

(4) It certainly seems probable, that arsenobenzol treatment which rapidly destroys accessible spirochaetes interferes with, or stops, the development of antibodies. While a single full dose of "606" can put an end to outbreaks of syphilis in skin or mucous membranes, it is much more likely to be followed by a neuro-recurrence than if the patient is treated with mercury alone, which permits the repeated outbreak of lesions of the skin and mucous membranes. The physician who would do his best for his patient must administer as much treatment as will make reasonably certain that the disease will not recur, and, in determining the amount of such treatment, he has no complete guidance in the progress of his patient. Many examples could be cited of cases in which the serum reactions became negative rapidly, but the patient developed skin or mucous membrane lesions within a few weeks of the treatment being suspended.

The original "606" has largely been superseded by preparations which, whilst being more kindly to the patient than was the first compound issued by Ehrlich, are undoubtedly more kindly to the parasite. Considerations of safety have led to the employment of individual doses of arsenobenzol which are smaller than those used originally, and each injection does not now effect as much towards the cure of the patient as it did before the war.

The routine treatment of syphilitic patients attending the V.D. Treatment Centre at St. Thomas's Hospital consists of:—

(1) For primary cases with a negative serum reaction, two courses each of ten arsenobenzol ("914," or stabilarsan) injections, totalling 6.3 grams "914," with ten one-grain injections of mercurial cream, each course lasting thirteen weeks, with an interval of two months between the two courses.

(2) For primary cases with a positive serum reaction, two such courses followed by one of five injections (totalling 3.3 grams, "914," and 5 grains of mercury) after an interval of two to three months.

For secondary cases, two ten-injection courses as above, followed by two five-injection.

For later cases, a number of courses of seven injections of each metal. More recently bismuth has been substituted for mercury, an amount containing 3 to 4 grams of the metal being given in the ten-injection and 1.5 to 2 grams in the five-injection course.

The records of patients treated on these lines confirm amply the view that "914" administered intravenously does not compare in therapeutic power with "606" according to its arsenical content (roughly 2 to 3), and they justify the very considerable increase of arsenobenzol in the above programmes over pre-war and war courses. Of the patients suffering from primary and secondary syphilis who have arrived at the stage of a positive Wassermann reaction and who had received not less than 5 grams "914" (generally 6.3 grams), between 30 and 40 per cent. gave a positive reaction. It is probable that "914," when administered intravenously, is excreted so rapidly that there is too little time for the spirochaete-destroying derivative to be formed. This is supported by the better results obtained from intramuscular or deep subcutaneous injections of "914." The amount of "914" used must be very much more than previous experience with "606" would lead us to believe would be necessary if this compound were used. Some workers give sufficient arsenobenzol and mercury or bismuth, to render the serum reactions negative, and then prescribe mercurial treatment for the balance of two years. The principle of this plan seems to be the belief that in any case two years' mercurial treatment will cure an early case of syphilis, and that the arsenobenzol makes a little more sure of the result. But two years' mercurial treatment cannot be relied upon to cure even an early case of syphilis. In the years before the war the blood of some hundreds of soldiers who had received the regular Army course of mercurial injections lasting two years was found still

positive to the original Wassermann test in over 40 per cent. of cases.

The results at St. Thomas's Hospital show the great difficulty of converting a positive serum reaction in old-standing cases to negative.

The process is tedious to both patient and physician, but it is just such patients with persistently positive reactions who die suddenly of syphilis of the cardiovascular system or develop seriously disabling diseases, such as general paresis and tabes, at ages when most men are of the greatest value to their families and community. Treatment is troublesome, but the disabilities which it prevents are much more so.

Dietary Control of Nephritis.

By MARTHA KOEHNE, M.A.,

Assistant Professor in Home Economics,
University of Washington, Seattle.

Jl. American Med. Assoc., April 11, 1925, p. 1103.

DIETARY limitations should always be carried out more strictly in acute nephritis than in chronic cases and in young people than in old people.

A. Proteins.—In general, the better the quality of the protein mixture in the diet, the smaller the amount needed for growth purposes and for maintaining nitrogen equilibrium. Proteins from animal sources—meat, fish, poultry, eggs, milk and cheese—are superior in quality to those found in cereals, legumes, fruits and vegetables. Not less than half the protein eaten should be of good quality.

Quantity: Two-thirds gram of protein per kilogramme of body weight is usually considered the minimum on which a person can remain in nitrogen equilibrium. This is possible, only if the quality of the protein intake is good.

It may be advisable, in some cases of acute nephritis, to give less than two-thirds gram of protein per kilogramme. Such a procedure should not be kept up more than a week or ten days, as a rule.

A patient should not be kept indefinitely on a protein intake as low as two-thirds gram per kilogramme, unless it is known that he is having difficulty excreting the end-products of protein metabolism, and that urea is accumulating in the blood. The normal urea content of the blood is from 20 to 40 mg. per hundred cubic centimetres. Concentrations over 50 mg. usually indicate retention of urea. In cases of urea retention in which the concentration of the blood urea does not fall on restriction of the protein intake alone, a low protein diet should not be kept up too long without trying other measures in addition.

If, as is usually true in nephritis, the question is chiefly one of how much protein, there is no real advantage of white meat, fish or poultry over red meats.

It is seldom advisable to give a nephritic patient more than 1 gm. of protein per kilogramme of body weight. The average normal intake for adults is from 1 to 1.5 gm. per kilogramme.

B. Carbohydrates, Fats and Calories.—The only restrictions in the use of such foodstuffs is that the total calories should not go above the amount needed for the production and maintenance of a weight somewhat below average for the patient's age, height, sex and body build. There should also be judgment used in the selection of carbohydrate-rich foods, the preference being given to those that are base-forming, such as potatoes and other vegetables, and most fruits, over those that are acid-forming, such as cereals and a few of the fruits and vegetables. Some fruits and vegetables contain organic acids, such as benzoic and oxalic, which the body cells cannot use as fuel, as they can citric and malic acids. The use of foods containing the former acids thereby increases the acidity of the urine. They should be omitted from the diet of a nephritic patient.

C. Fluid Restriction.—In the early stages of acute nephritis, if the patient is oedematous, fluids should be

restricted to 1 quart. If no œdema is present, $1\frac{1}{2}$ quarts may be allowed. In chronic nephritis, the fluid intake may go up to 2 or even $2\frac{1}{2}$ quarts, if œdema is absent. If œdema is present, not more than $1\frac{1}{2}$ quarts should be allowed.

"There is no proof, to date, that the kidney has more difficulty excreting concentrated substances than very dilute ones." Why, then, give unlimited amounts of liquids when the kidneys cannot excrete them?

D. Sodium Chloride Restriction.—Not all cases of œdema are cases of salt retention, but all cases of salt retention are œdematous. The degree of salt retention necessary is proportional to the amount of such œdema.

1. Salt-free diets are reserved for very acute cases in which, for a week or ten days, the amount of food a patient eats may be disregarded. Such diets are not used in chronic cases, or in acute cases not accompanied by œdema. They should not be used longer than two weeks. The reasons are that:

(a) The patient will not be able to eat enough food because of its extreme unpalatability.

(b) Persistent salt starvation may lead to another type of œdema and prove fatal.

2. Salt-low diets are commonly used in chronic nephritis accompanied by œdema, as well as in acute nephritis. If moderate amounts of salt are used in cooking, and if no salt-rich foods are used, and no salt added to food at the table, the average intake of sodium chloride is from 5 to 6 gm. a day (8 ounces of milk contains approximately 0.5 gm. of sodium chloride).

E. Diuretics and Stimulants.—Tea, Coffee, and Alcohol: Young people with acute nephritis ought not to be allowed to use such substances. Very weak coffee or tea may be used occasionally. Old people, however, with either acute or chronic nephritis, need not be compelled to give them up entirely, provided they use them in moderation. The reason is that such people have become so accustomed to using them that prohibiting their use would result in a restlessness and dissatisfaction that would be far more injurious than their use.

In general, diuretics should be avoided when the kidneys are excreting water with difficulty. As has been said, "Why whip up a lame horse?"

F. Condiments and Spices.—These should be omitted from the diet because of a possible irritating effect on the kidney in excretion. Natural flavours of foods should be relied on.

G. Acid-Base Balance of Food.—Sansum and Blatherwick contend that the elimination of excess acids produced by the regular use of the common acid-forming diets is injurious to renal tissue.

They recommend reduction of cereals, meats, fish, poultry and eggs, the liberal use of most fruits and vegetables, and milk in adequate amounts. The required number of calories can then be made up with neutral fats, starches and sugars.

The treatment of Sprue.

By H. HAROLD SCOTT, M.D.,

London School of Hygiene and Tropical Medicine.
Lancet, March 21, 1925.

CASES of sprue occur where persons who have lived abroad enjoying good health begin to show symptoms of the disease months, even years, after they have retired and settled down at home. Some of the symptoms present in true sprue, such as loss of weight and fatty diarrhœa, are found in other diseases, and also a matter of greater moment.

The most recent form of treatment, based on the results of laboratory tests, is that by calcium and extract of parathyroid gland. The regulator of calcium metabolism is believed to be the parathyroid glands, and this is borne out by the fact that if parathyroid extract is given in doses of one-tenth of a grain twice daily, the symptoms of sprue have been shown to clear up with marvellous rapidity. The ulcerative stomatitis may disappear in ten days or so, the diarrhœa is re-

placed by constipation, the colour begins to return to the stools in two to three weeks, the patient puts on weight, often 3 to 4 lb., sometimes as much as 7 lb., in a week by the end of a month, and his sense of well-being is restored.

The technique of estimating the ionic calcium by Vines's method is as follows: Blood is taken in a glass tube, about 1.5 to 2 c.cm., and allowed to clot. The serum, of which about 1 c.cm. is needed, is then separated and heated in a water-bath to 56° C. for an hour. The steps in the test are three: In the first, by adding fixed amounts, 4 vols., of various dilutions of ammonium oxalate to 10 vols. of fresh normal blood (usually that of the person carrying out the test) and placing the mixture in the thermostat at 37° C. for ten minutes, that strength of oxalate is found which just prevents clotting under the terms of the experiment. The next step is to find out by adding 2 vols. of various dilutions of calcium chloride to fresh arrangements of the above mixture (4 vols. of the determined oxalate dilution and 10 vols. of blood), what dilution of calcium chloride just suffices to bring about complete clotting of the blood. The third step consists in carrying out tests similar to the last but replacing the calcium chloride solution by the same volume of dilutions of the patient's serum, prepared as previously described. By a calculation the calcium content of this serum is thus determined, and in normal subjects will be found to be somewhere between 10.4 and 11.4 mg. per 100 c.cm. In severe sprue it is about 6.5 mg., and after the treatment to be detailed shortly is begun, if this test of blood is carried out weekly, a steady progress is noted, till, at the end of four to six weeks, it is found to reach normal. The theory in part is that one of the actions of the parathyroid glands is to counteract intestinal toxins; that it carries on this work until the toxins are too great for it to cope with. Under these conditions, if the toxins can be reduced, as by careful dietetic regulation, the glands can recover and perform their function again, at least for a time. If, by good fortune, one of the chief causative organisms is isolated and a vaccine made, the administration of this may relieve the gland for a time, hence the good results of some vaccines in some cases and of other vaccines in other cases, as mentioned above; hence, also, the failure of vaccines in the hands of many, some other than the toxin-producing organism having been isolated.

The usual line of treatment by this most recent method is to put the patient to bed for the first 14 days, allowing milk only, beginning with $3\frac{1}{2}$ to 4 pints a day, taken warm (not hot) with a teaspoon, at regular intervals, and increasing by $\frac{1}{2}$ pint in the 24 hours, till at the end of the fortnight 7 to $7\frac{1}{2}$ pints are taken daily. Calcium lactate is also given in cachets containing 15 gr. each, thrice daily, and parathyroid extract gr. $1\frac{1}{10}$ twice daily. It is absolutely essential that the extract be free from thyroid. If there is constipation a small dose of liquid paraffin is probably the best aperient. From the tenth day onwards some plain biscuits may be allowed, such as water biscuits or Mellin's food biscuits. By this time the ionic calcium has probably increased to between 7 and 8 mg. per cent., and gradual increase in food may be allowed and the patient permitted to be up for an increasing time each day. At the end of three weeks the patient, unless a very severe case or one of long standing, can take milk-puddings, eggs, fish, potato, carrot, bananas, and in the fourth week chicken and non-acid fruits. The calcium can be reduced in the third to fourth week and probably stopped altogether at the end of the fourth. The parathyroid extract should be continued in full doses till the fifth week, then reduced to half doses for a week, and in most cases further reduced until it in turn is stopped altogether at the end of six to seven weeks. This, however, can only be gauged with certainty by the blood test, and the drug must be continued until this shows that the ionic calcium has reached the normal.

It will be found that any return of symptoms, whether due to dietetic or other indiscretion, will be

evidenced also by a fall in the ionic calcium, hence the enormous value of the test as a gauge of progress in this disease.

Though it is perhaps, too early to claim permanency of cure, several of those who had been invalidated home and forbidden to return to the tropics have, nevertheless, gone back and remained perfectly well, and equally good results have been recorded of patients treated in the endemic centres of the disease.

Treatment of Septicæmia.

Lancet, March 28, 1925.

At a combined meeting of the Sections of Surgery, Medicine, and Pathology of the Royal Society of Medicine held on March 24th, with Dr. Robert, Sir Thomas Horder opened a discussion on the treatment of septicæmia. He said that his views on this subject differed little from those he held ten years ago. The nature of the infecting organism naturally bore on the treatment, and the two common cocci involved were the *Streptococcus pyogenes vel hæmolyticus* and the *Staphylococcus aureus*. He classed the methods of treatment into three main groups: (1) General or non-specific measures, (2) bacteriotherapy, (3) chemotherapy.

General or Non-specific Measures.—This group comprises: (a) Rest, both of the individual and of the region of the primary focus, if this was ascertainable. (b) Fresh air, to the extent permitted by the patient. (c) Sunlight. (d) Diet, which should be free, fluid at the height of the infection but containing many calories. (e) Reassurance, including the general attitude towards the patient and his complaint. (f) Hydrotherapy, about which there was considerable difference of opinion. In America this was more extensively used than in this country. (g) Elimination, with attention to bowels, skin, and kidneys. (h) Sleep. (i) Anodynes, among which he recommended opium, suggesting that we were too loth to use this drug nowadays. (j) Treatment at the site of infection, drainage, elevation, which gave much relief, heat, in the form of continuous baths or fomentations, and antiseptics. He was opposed to the use of very strong antiseptics which might interfere with the vitality of the tissues. (k) Intravenous infusion in acute cases. (l) Transfusion of whole blood, of which he had not had much experience. (m) Drugs, which were useful, but must not be relied on alone. He put first arsenic, preferably in the form of sodium cacodylate, one grain in one c.cm. of a saturated solution of nucleic acid or sodium nucleinate, given twice daily intramuscularly throughout the whole course of the disease. The smell of the breath showed when the patient was saturated with it. After that came opium and then such other drugs as quinine, strychnine, digitalis, and the hypnotics.

Bacteriotherapy.—This took the form of immune sera, bacteriological antigens, or combined methods. Sir Thomas Horder was accustomed to give an initial dose of not less than 50 c.cm. of univalent antistreptococcal serum intravenously on the first day, repeating it on the second, perhaps on the third day. By that time an autogenous vaccine could usually be prepared, the sensitised type being the most advantageous form, given in doses of 100 million the first time, 250 million on the third day, and 500 million on the fifth or sixth day. In "immunogen" an attempt had been made to get certain products of auto-digestion of the micro-organism as well as the endotoxin, and this substance was worth trying.

Chemotherapy.—This took the form of chlorine or coal-tar derivatives, metals, or colloidal metals. These had proved disappointing. In the staphylococcal form of the disease the infection was more pyæmic, giving more time, but having the disadvantage that no serum could be prepared. The treatment of chronic septicæmic processes such as ulcerative endocarditis was as disappointing to-day as ten years ago; the best line to take was that of using all possible non-specific methods, especially sunlight.

Sleep and Sleeplessness.

By C. P. SYMONDS, M.D., F.R.C.P.

British Med. J., May 9, 1925.

The Treatment of Insomnia Drugs.

NARCOTICS are of great value in the treatment of insomnia for two reasons: First, the toxic effect of insomnia upon the cortical nerve cells may be more severe than that produced by the drug. Insomnia may lead to depression of the higher mental faculties, and eventually to coma and death. In the second place, small doses of narcotics often facilitate the onset of true sleep. Bromide alone, or in combination with chloral; paraldehyde for a quick action; sulphonal for delayed effect; medinal as a useful all-round narcotic; the coal-tar analgesics and opium for pain or discomfort, comprise the therapeutic stock-in-trade.

Habit Formation.

Of the value of conditioned stimuli in facilitating sleep I have already spoken. Most of us have a ritual of some kind which stands us in good stead when sleep is threatened; it includes the whole business of undressing and getting into bed; the habit of reading in bed is often a part of it. For this reason an invalid, whenever it is practicable, should sit up in a chair just before bedtime while his bed is made, so that he may not altogether miss the experience of going to bed.

Unfortunately, when sleeplessness has persisted for any length of time the old rituals lose their value, and may even facilitate insomnia. Then is the time to initiate new rites, beginning by moving the patient, if not into another house, at any rate into a fresh bedroom. The ritual may consist of some such sequence as the following: a warm bath, into bed, a cup of warm milk or an equivalent, then a solemn plugging of the ears with cotton-wool, perhaps five minutes' reading by the bedside lamp, and then lights out. The sleeping draught, if any is prescribed, may be taken before or with the warm drink. As a finishing touch, the repetition by heart of some soporific verse. Keat's Ode to Sleep is insurpassable in this respect. Such a ritual must be persevered in if it is to be efficacious.

Muscular Relaxation.

Sleep, as we have already observed, is incompatible with any great degree of muscular tension, and there are some individuals who are kept awake largely by their inability to relax their muscles. The tendency for the sleepless person being to toss and turn, it is important that he should learn that this in itself is fatal to sleep, and that the wisest plan is to lie perfectly still. Even though this may demand a certain amount of effort and self-control, it will often induce sleep.

The efficacy of this principle in treatment has been shown most clearly in certain cases of encephalitis lethargica in children, where motor restlessness has been the most prominent symptom of the insomnia. After the preliminary rites of warm bath, sleeping draught, and ear plugging, the child is tightly rolled in a long sheet which is fastened with safety-pins, the arms being included so that he is immobilized. The results in some cases have been striking—for instance, a sleep of nine hours with the pack, as compared with a maximum of four and a half hours when the other measures alone were employed.

Beyond this, there is an art in muscular relaxation, as anyone may prove by attempting to allow one of his limbs to be absolutely passive in the hands of another person. It is an art which patients can be taught to acquire limb by limb until they can themselves practise complete bodily relaxation. The soporific effect of this exercise is sometimes of great value; it may be taught by an instructed masseuse, and may be usefully included among the final stages of the bedtime ritual.

Details of Treatment.

The insomnia due to disease of the sleep centre, such as occurs in encephalitis lethargica, is, the most difficult of all to treat. In many cases, as the normal sleep

time comes round, the cortex appears to pass into a condition of great overexcitement, and this occurs night after night for many weeks with the greatest regularity. It is tempting to believe that in these cases reflex inhibition has been converted by the disease into reflex excitation, and that the cortical cells are thus being abnormally bombarded with afferent stimuli. A combination of drugs and ritual, if persisted in for a long time, sometimes appears to be effective, and immobilization, as already described, is valuable in patients with great motor restlessness. But these cases are, on the whole, disappointing.

The toxic and infective group of insomnias should be treated on the same lines. Here the direct effect of the toxins upon the cortex is, as a rule, reinforced by sources of pain and discomfort. Opium therefore is the most useful drug, and, in cases which are likely to be of short duration, may be used freely. In the chronic cases small doses of medinal combined with aspirin are useful. It is in dealing with this group of cases, however, that it is most important to remember the poisonous nature of the narcotic drugs. The ritual therefore should be made use of as far as possible, and the dose of drugs kept low.

The third group of insomnias—that in which sleep is prevented by unwonted stimuli—offers most scope for treatment. Pain and discomfort must be treated by local measures, and, if necessary, with drugs—*aspirin* or *opium*.

The emotions which have most power to disturb sleep are naturally those which are painful. Paramount are fear and anxiety. We may further distinguish between the open and hidden emotion.

A. An emotion which is present to the waking mind—a declared worry with all its associated memories hinders the onset of sleep.

B. An emotion which has in the waking state been prevented from exciting conscious activity (that is, in the psychological sense, a repressed emotion) may cause insomnia in either or both of the following ways:—

(1) Either the subject finds himself thinking furiously upon some indifferent subject in order to prevent the repressed worry from reaching consciousness, and so is unable to go to sleep; or

(2) He may go to sleep, but is awakened by the repressed emotion forcing its way into consciousness, often in the shape of a dream or nightmare.

The distinction between these two forms of worry—the superficial and the deep—seems to have been present in the mind of Keats when he wrote in his *Ode to Sleep*:—

"Then save me, or the passed day will shine
Upon my pillow, breeding many woes;
Save me from curious conscience, that still lords
Its strength, for darkness burrowing like a mole."

It the latter type of case, in which insomnia is due to repressed anxiety, much can be done by means of judicious analysis and psychotherapy. Free ventilation and frank discussion of the underlying emotional conflicts is the essence of successful treatment.

The open worry, as a rule, is short-lived and resolves itself. Being of an occasional nature it may be justifiably treated with drugs. A whisky and soda at bedtime is often sufficient. It is most important, however, that sleeplessness of emotional origin should be taken in hand early, for the habit of insomnia is readily acquired, and we are then apt to encounter as a perpetuating cause of sleeplessness the anxiety about sleep. The patient goes to bed with the fear that he will not sleep, and this fear, gathering around it thoughts of the morrow's duties, successfully inhibits the sleep reflex and excites cortical activity. This fear must be treated from the start with absolute reassurance. As a cause of unpleasant symptoms the importance of insomnia must be minimized in the patient's sight. Finally, in a case in which this particular anxiety appears to be mainly responsible for the trouble, the patient may be given an effective draught—a drachm and a half of paraldehyde or $7\frac{1}{2}$ grains of medinal, with the assurance

that he will have a good night's sleep. If this follows, the same draught or cachet should be placed by his bedside on subsequent nights, with instructions that he should take it, *without hesitation*, if he is unable to sleep. If the case has been judged correctly this line of treatment succeeds. The presence of the drug by the bedside in itself allays the anxiety, and the patient sleeps soundly without taking it. After a few nights of this kind he ceases to bother about the drug, and as far as his insomnia is concerned may be considered cured.

In the treatment of the emotional insomnias bedtime ritual and muscular relaxation are both of value; the former may also be made a vehicle for reassurance; the latter is most useful in those individuals whose anxiety reflects itself in muscular tension. But the narcotic drugs are also essential in the majority of cases. That they should be at the same time more beneficial and more permissible in this than in other types of insomnia is intelligible in the light of our theory. Here we have the sleep reflex prevented by stimuli arising within the nervous system at a high level of cerebral integration. The cells in which these stimuli arise are therefore themselves susceptible to narcotic drugs in much the same degree as those cells which we have supposed to be concerned with consciousness.

Drugs may be given regularly, at first in sufficient doses to ensure sleep, while at the same time the other therapeutic measures of psychotherapy, habit formation, and relaxation are employed with the object of re-establishing the natural rhythm. After the patient has had a succession of four or five good nights the dose is gradually reduced, the other measures, of course, being continued. In employing this method of treatment we are liable to encounter one of two difficulties—the patient is liable, on the one hand, to develop anxiety lest he become a drug habitué, or, on the other hand, when he finds that his dose is diminished, he may be kept awake by the renewed fear that to-night he will not sleep. The patient should be told that the dose will be reduced without his knowledge. This is easily done if the medinal is given in cachets. The size of the cachet and the amount of its contents are kept constant by replacing the medinal subtracted by sodium bicarbonate. The patient may thus be allowed to go on taking the cachets until he can be told he has now been sleeping soundly on nothing but sodium bicarbonate for several days. Or the cachet may be incorporated as a part of the bedtime ritual for some time longer before the disillusionment is completed.

Diabetic Treatment Simplified.

By FRANK C. EVE, of Hull.

British Med. Jl., June 6, 1925.

In this paper Dr. Eve gives instructions for the home treatment of diabetes.

"The ground can be cleared by distinguishing clinically between cases of simple glycosuria, which are common and usually unimportant, and stubborn diabetes, which is uncommon and serious. This paper deals with genuine diabetics who are living at home.

Insulin.

The main practical points are:

1. Insulin is something which somehow enables a diabetic to burn up sugar like a normal person but does not enable him to store it as glycogen.

2. Insulin can in this way cause the blood sugar to sink to a dangerously low level (hypoglycemia). This danger can be guarded against if the patient always carries about with him eight large lumps of sugar (1 or 2 ounces of barley sugar—Macleans) and promptly eats them all if he feels queer after an injection of insulin. Two grams of glucose are supposed to keep busy one unit of insulin; from which it is reckoned that eight average lumps of sugar would act as antidote to 15 units of insulin.

3. Insulin is given two or three times a day, just before a chief meal, which if possible should contain

Nov., 1925.]

1 ounce of bread; 10 to 50 units daily is the usual range of dose; more is seldom useful.

4. The patient can be taught to inject it into the pinched-up skin of the thigh, under weekly supervision.

5. Insulin has to be acid; in a few subjects this causes painful lumps. It is said that neutralization in the syringe by sterile sodium bicarbonate solution of proper strength prevents this irritation and does not impair the action of the insulin.

6. As to blood tests with insulin, these are rarely found helpful, for it is unattainable in private practice to keep the blood sugar normal. You dare not even keep the urine quite free of sugar in insulin cases.

7. The risk of giving insulin in unsuitable cases will be practically eliminated without blood tests (a) if you first try to cure all cases by diet alone; (b) if ketones are present, and abundant sugar, insulin is surely needed; (c) leaky kidneys (renal glycosuria) are a real but uncommon danger. These cases may be recognized by their uncanny failure to improve with diet, by their good health, by the absence of ketones, and by the absence of glycosuria three hours after a good starchy meal. A blood sugar test will decide the matter by showing a low renal threshold for sugar.

8. Ill effects attributable to insulin are rare while the benefits are notorious, but if in an emergency you are nervous of causing hypoglycæmia you can guard the insulin with sugar, as above.

Ketones.

Ketones, such as acetone and diacetic acid, are half-oxidized fats. Their presence in the urine is revealed by the nitro-prusside test or the ferric chloride test; the former is too sensitive and becomes a scaremonger so the latter is preferred.

If the addition of two drops of liq. ferri perchlor. fort. to the urine produces a dark-brown colour then ketones are present in dangerous amount, and must be got rid of, lest coma supervene. Ketones are far more pregnant with danger than sugar, and are often produced by too strict a dietary.

To get rid of ketones, it is often needful not only to give extra carbohydrate, but also give insulin, which has the mysterious property of enabling the diabetic to burn up sugar like an ordinary person. So that if ketones appear, watch for coma, ignore the sugar in the urine, and treat the much greater danger by giving alkalis freely and more bread. And if you find that large doses of alkali fail to make the urine alkaline, then the peril of coma is menacing indeed. Ten grains of sodium bicarbonate should alkalize a normal urine; so try your ketosis patient with 20 grains. An hour afterwards boil and cool the urine in a test tube and test with blue litmus paper.

There is no time in coma to tifle with half-measures. Hence intravenous injections are needed, starting with 20 to 40 units of insulin, 40 to 80 grams of glucose in 800 to 1,600 c.cm. of water. Then you must feel your way by results, but 80 to 100 units or even more may be needed in the first day. Croton oil, strychnine, and camphor will also probably be indicated.

Exercise.

Exercise in moderation is important in diabetes to help the combustion of sugar to carbonic acid which takes place in the muscles. Gardening is an excellent hobby for diabetic patients, and often makes them look the picture of bronzed and ruddy health. Bed should be prescribed only during starvation or illness.

Method of Domestic Estimation of Urinary Sugar.

The apparatus required is: (1) A urinometer with a long stem indicating clearly specific gravities 1000 to 1050. This, and its glass cylinder, should have a case for travelling. (2) An engineering student's exercise book of squared paper. Its left-hand margin is also graduated 1000 to 1050. (3) A thermos flask, pint size. (4) A pennyworth of yeast, fresh twice a week.

Method.

Every night the specific gravity of the urine is taken when warm. The thermos flask, which has been warmed and cleansed with hot water, is filled with the warm urine; a piece of yeast the size of a small walnut is added and shaken up. The flask is corked loosely (or with cotton-wool) and wrapped in blanket. Next morning the specific gravity is again taken. It will be less, because all the sugar has been converted by the yeast into carbonic acid gas (mainly). Let us suppose the gravities before and after fermentation were 1040 and 1020. A red dot and a black dot will be placed at their proper heights in the first column of the squared page. Next day another pair of dots will appear in the next column. Thus will be spun out an upper and a lower curve, one red and the other black. The space between these curves represents the excretion of sugar in grains per ounce. The object of treatment is to pinch these two curves together. When they coincide there is no sugar, and it is well to mark these days by a red dot within a circle.

If the morning urine alone is recorded the results will be more constant, more flattering, and less useful. The night specimen is best for a patient who does not always urinate at home. A twenty-four hours specimen is not much better; it is a nuisance to warm, and is only available for the home-keeping patient.

Ketone Test.—Every morning the patient watches two drops of liquor ferri perchlor. trickle down the near side of the urine glass. If it changes from yellow to dark brown the doctor must be informed that day."

Sodium Chloride Treatment for Vomiting.

LEHMAN AND GIBSON in the *Journal of the American Medical Association* of April 25, 1925, record a series of 15 patients suffering from symptoms of reverse peristalsis in the upper gastro-intestinal tract from various causes. All were given amounts of 2 per cent. sodium chloride solution varying from 50 to 200 c.c. In every case there was immediate relief of symptoms, but in several cases the relief was transient.

Nephritis with œdema signifying chloride retention is an important contraindication. An overdose must be avoided in any case on account of the danger of a salt diarrhœa. On account of the popular use of warm saline solution as an emetic it was given cool or cold.

Human Schistosomiasis in India.

By J. P. CULLEN, M.D. (Lond.), D.P.H.

Jl. Trop. Med. and Hyg., Dec. 15, 1924.

"WHILST this article is mainly concerned in calling attention to the fact that *Schistosoma japonicum* constitutes a serious menace to the Indian Empire, I think it is worth while placing on record that since the original case of *Schistosoma japonicum* was discovered by me in the early part of the present year, and attention called to its occurrence in the border territory between Yunnan and the Northern Shan States of Burma, eight further cases have been noted during a period of six months; the first of these cases was treated with antimony tartrate, in what may be now regarded as the orthodox manner, with the result that after a total dosage of 12 grs. ova had disappeared from the fæces, the liver had regained its normal dimensions, and tenderness over the organ was absent, whilst the spleen, which had previously been enlarged to four-fingers breadth below the costal margin could only just be felt below the ribs. Whilst not prepared to say that after 12 gr. of antimony tartrate the man was cured, yet, in my opinion, he was well on the way to recovery when I left the Northern Shan States at the end of September. As regards the remaining cases in this list they were considered to be too far advanced for specific treatment, suffering as they were from emaciation and marked ascites it was also thought

impolitic to lose native confidence by treating hopeless cases.

I wish here to draw attention to the following points:—

(a) That Asiatic schistosomiasis is more widely spread than is generally supposed, or recorded in text-books on tropical medicine. For example, the most recent authorities state, as the result of their questionnaires, that 'the mountainous areas embraced in the provinces of Kiangsi, Kweichow and Yunnan, as well as those portions of the south-eastern coastal provinces lying above the coastal plain, report no cases.'

(b) That accurate determination of the distribution of the disease and of its intermediate hosts is necessary. Personally, as regards Yunnan and the Northern Shan States, it appears to me that the country adjoining the Shweli river affords the most promising field for investigation.

(c) That on location of foci prophylactic measures to prevent the spread of the disease in India are necessary. Such measures to involve close collaboration between the tropical expert and the sanitarian.

Whilst statistics of the extent of the disease in a country like China must necessarily be open to many criticisms, it is worth while noting that Professor Faust estimates that 10,000,000 people suffer from the disease in the Yangtse-Kiang watershed and 20 per cent. of that number die from its direct effects. F. Milton, in a private communication, reports that *Schistosoma japonicum* is probably present on the west coast of India, and the fact that India is not only threatened but already infected on the eastern border is a matter affording grave food for reflection on the part of the authorities concerned."

Endocrine Therapy.

British Med. Jl., April 11th, 1925.

At a special discussion at the Royal Society of Medicine, on March 31st, on endocrine therapy, Dr. W. Langdon Brown said that endocrine therapy might have as its object the replacement of a deficient internal secretion, in which case they were on sure ground with thyroid extract and insulin, on less sure ground with parathyroid and pituitary extract, and on very doubtful ground with other glandular preparations. But it might also have as its object the employment of some extract simply for its pharmacological action, such as adrenaline for its local vaso-constrictor effect or pituitrin for its stimulating effect on plain muscle. He would also include under endocrine therapy the use of other drugs which, by their influence on the endocrine glands, enabled those glands to carry out more successfully their normal function; he instanced iodine medication in diseases of the thyroid. As to methods of administration, apart from thyroid extract and (less constantly) pituitary extracts, the effect of oral administration was very uncertain. Nasal administration had met with a certain degree of success in the treatment of diabetes insipidus, by pituitrin. Of rectal administration very little was known. By subcutaneous or intravenous injection, adrenaline, pituitrin, and insulin could readily produce powerful effects. Grafting and transplantation methods were still on their trial. It would appear that such grafts were treated by the organism as foreign bodies and became absorbed, so that their effect was only temporary.

His conclusions were that thyroid medication had the widest application of all the endocrines and was the easiest in practice. Parathyroid extract he had found of great service in tetany and gastric ulcer. Adrenaline was of little if any use in substitution therapy; it was of great use for its local effect on blood vessels and for its effect on plain muscle. Pituitary extract was of doubtful value, though it might occasionally alleviate Fröhlich's syndrome and adiposis dolorosa. It was useful in asthma and as a temporary cardiac stimulant. Insulin was of proved value in diabetes, and here he protested against

the statement that if insulin was once given it must be continued for the rest of life. He had a number of patients who came under early treatment with it, and who were keeping free from glycosuria, with a normal blood sugar, although insulin had been discontinued for periods varying from three months to over a year. The existence of an ovarian hormone he regarded as proved, and it should not be beyond the wit of man to prepare a reliable extract. It was doubtful whether the present commercial preparations were active, but he had seen great benefit in thymic asthma and in a case of epileptiform seizures accompanied by temporary swelling of the thyroid. In conclusion, Dr. Langdon Brown said that he doubted whether any orchitic extract was effective.

Professor Swale Vincent declared that the present boom in endocrine therapy was an evil of the same general nature as the indiscriminate sale of patent medicines. But whereas in the latter case it was the members of the general public who were so continually duped by the vendor of the drug, in the former the distressing spectacle was to be witnessed of hundreds or thousands of medical men being cajoled into prescribing preparations which were nearly always of doubtful value and were often quite inactive in health or disease.

He asserted that in the case of the great majority of these preparations there was no evidence that any effects whatever were produced when they were given in the ordinary way by the mouth—unless in such quantities as to serve as foods!

Discussing certain preparations singly, he said that, of course, there was no need to emphasize the value of thyroid preparations in myxœdema and cretinism. In lesser degrees of hypothyroidism and in rheumatism, rickets, mental diseases, and other conditions these preparations might also be useful on the general principle that a drug which stimulated the chemical activity of the whole body might be applicable in a variety of morbid conditions. The results of parathyroid medication were still very uncertain. Commercial preparations of ovary and parathyroid at present on the market were, according to the majority of competent observers, physiologically inactive, and in all probability useless as therapeutic agents. It had never been demonstrated in a satisfactory manner that treatment by pituitary extracts had any effect in remedying the symptoms thought to be due to pituitary insufficiency. Posterior lobe preparations were useful as drugs in the treatment of diabetes insipidus and to aid contractions of the uterus, but these uses had no relation to any known function of the organ, and were not instances of a substitution therapy. Physicians who continued to prescribe preparations for the use of which there was no scientific basis and no sound clinical evidence were guilty of conduct unworthy of modern medicine.

Mr. Kenneth Walker confined himself to discussing the therapy of the testis. The effort to obtain results from the oral administration of testicular extract had failed, and this had led to the use of testicular grafts. He referred to the work of Voronoff, who had now made some fifty or sixty transplants into the human subject from the higher apes, and claimed to have obtained valuable results. The grafts had been undertaken for various conditions—eunuchoidism, senility, neurasthenia and sexual neurosis—and the chief benefit was said to be in the direction of improvement in the general health, increase of mental and muscular vigour, and stimulation of hair growth. Improvement was less definite in cases grafted for impotence or sexual neurosis. Other workers in this field had preferred to use human transplants, and had derived their material from newly executed criminals, patients dying of accidents, the cases of ectopia testis in which the removal of the misplaced organ was justified. It was from this last source that the speaker had himself obtained his grafts. The technique of transplantation was not difficult. Personally, he thought that Voronoff's use of a serous cavity like that of the tunica vaginalis for

implantation was the best. Mr. Walker believed that vascularization and survival of the graft was an actual fact. At the same time, a steady atrophy of the engrafted material no doubt occurred, and the actual life of the transplant was, he thought, considerably shorter than that claimed for it by Voronoff. He would feel happy if he could be sure that complete atrophy did not occur within eighteen months. This, however, did not necessarily mean that at the end of that period all benefit was lost. A graft might stimulate the growth of existing testicular tissue or the hormone supplied by the graft might tide the patient over a critical period until compensatory changes in other endocrine glands succeeded in restoring the endocrine balance. In conclusion, he said a few words about vaso-ligation as a means of stimulating the activity of the testis. Those familiar with Steinach's experiments on aged rats must certainly be impressed by the results of vaso-ligation. In human beings the results of the operation had been less certain. In many cases there had been no benefit; in some the general health and mental vigour of the patient had improved, and in a few cases the results had been still more striking. The speaker had performed Steinach's operation in some fifteen cases, and, although it was difficult to eliminate the element of suggestion, he believed that in at least half of them an improvement in general health and mental vigour had taken place. He was particularly inclined to recommend the operation in the treatment of that hopeless malady of later life, paralysis agitans.

Sciatica.

A New Method of Treatment.

By CHARLES ROSENHECK, M.D.,
and

HARRY FINKELSTEIN, M.D.

Jl. American Med. Assoc., March 28th, 1925, p. 939.

Varieties of Sciatica.

In a previous study on the treatment of sciatica by perineural infiltrations and epidural injections, we classified sciatica as follows:—

Class 1.—Symptomatic or pseudo sciatica: due to recognizable infections, toxemias, constitutional diseases, exposure to sudden temperature changes, pelvic disturbances and organic nervous disease.

Class 2.—Orthopedic sciatica: an arbitrary division due to recognizable orthopedic conditions; viz., spondylitis deformans, lumbosacral, sacro-iliac subluxations and disease and affections of the hip joint.

Class 3.—Sciatica neuritis.

We have since learned that Sciatic neuritis is common end-result of the so-called "orthopedic sciatica," and in practically all the cases observed the underlying orthopedic affection was sacro-iliac disease—either traumatic or infectious.

The pain does not help us in differentiating the pseudo from the true form of sciatica, since this symptom is present in both conditions. Certain well-defined objective phenomena assist in arriving at a conclusion. In the order of their importance they are:—Tenderness along the course of the sciatic nerve; tension or stretching the nerve, thereby inciting pain, as in the well-known Lasague manoeuvre; flexion attitude of the involved limb; muscle hypotonia or atrophy, and scoliosis of the lower spine. Separate mention should be made of the depression or abolition of the Achilles' reflex, since this sign is a most valuable one, indicating—in the absence of cord disease—a degenerative process of the sciatic nerve; in other words, a true neuritis.

The treatment of the pseudoforms implies the detection of a wide variety of affections that may be responsible for the sciatic pain and the proper therapeutic applications to these underlying affections. The therapeutic task in the so-called "orthopedic sciatica" is a relatively simple and uniform affair as contrasted with those cases that occur from conditions of a widely diverse aetiology.

The method of epidural injections found instant favour and was extensively used by the French; but the majority of patients were soldiers exposed to the rigors of warfare and trench life, and in whom an infectious radiculitis of the sciatic roots was postulated.

In the light of these facts, one can readily understand the ready response of these cases to injection therapy. scant reference is made of cases of sciatica of orthopedic origin. Evidently foreign observers consider the relation between orthopedic affections and sciatica a minor one.

The authors' treatment is somewhat according to the type of case.

In Static Cases.—These are recognized by weak feet, hollow lumbar spine, pendulous abdomen, general lack of muscular tone, and vague sciatic pains. Supportive measures are best in these types, including proper orthopedic shoes, elevated on the inner side, and corsets constructed to support the relaxed or pendulous abdomen and to diminish the lumbar lordosis. Preference is given to the plaster-of-Paris corset, applied in a Sayre suspension apparatus, which can be changed in several days to an open corset, added corrective force being obtained by excising a 1 to 2 inch strip in front, inserting hooks and lacing tightly. This is augmented by instituting massage, electricity and graduated exercises to the weakened feet, and the abdominal and spinal muscles.

Traumatic Cases (acute).—These are recognized by sudden onset following injury direct or indirect, pain usually in one sacro-iliac region and extending downward along the course of the sciatic nerve, flattening of the lumbar spine, listing to one side, Kernig's sign, etc. This group is treated by rest in bed and support beneath the lumbar spine and the affected knee, followed by strapping the back with adhesive plaster or preferably by a plaster jacket as previously described, forcing the spine into hyperextension.

Chronic Cases.—These include the previously mentioned types that have not responded to the treatments described. This group, in spite of conservative methods of treatment over a prolonged period, fails to respond in the slightest degree. It is recognized by a chronic course with frequent acute exacerbations, intense suffering, weakness in the lower spine, severe sciatic pains, spasm of the lumbar and hamstring muscles, and scoliosis. These patients are destined to prolonged invalidism, and cannot pursue their vocations. In this group the treatment *par excellence* is the manipulative treatment of Baer and Coffield. The technic of the operation is as follows: The patient is placed on a solid, non-movable table, flat on his back, and is anesthetized to the point of complete muscular relaxation. Two assistants firmly hold down each side of the pelvis. The operator grasps the unaffected limb with one hand in front of the knee, the other above the heel. The hamstrings on the normal side are usually found slightly contracted. Gradually increasing force is then exerted in an anteroposterior plane, all rotary movements being avoided. This force is continued until the hamstring tension is overcome—Kernig's sign being negative. The affected limb is then grasped, in which the hamstrings are usually found in a state of marked contraction. Force is now exerted in an anteroposterior direction until the toes are approximated to the shoulder of the same side. Usually a distinct click is heard, which is a signal that the muscles have been sufficiently stretched.

Following the complete stretching, a stockinet shirting is applied, and the patient is turned face downward across two tables about 3 feet apart, one assistant holding the legs, the other the shoulders; the operator forces the lumbar spine into complete hyperextension, and pressure is exerted over the affected sacro-iliac joint. Felt padding is inserted, reaching from the mid-dorsal region as far down as the great trochanters, and a strong plaster jacket is applied, the hyperextension maintained by two bent steels. When hardened, the plaster is trimmed and the patient returned to bed either in the prone or the supine posture—in the latter

position, a pillow being placed under the lumbar curve. This case is worn for about two weeks, and on removal either a short open plaster jacket is substituted or a sacro-iliac corset. The latter should be worn for protection at least a year, the patient being warned to avoid undue muscular exertion.

The after-treatment consists of baking, massage and graduated exercises to increase the muscular tone. The results of this method of treatment are exceedingly gratifying. Baer states that in 100 cases manipulated, immediate relief was obtained in almost every case, there being only three relapses. The authors' observations in a similar series show favourable results in all cases of sciatica due to static disturbances or traumatic lesions of the sacro-iliac joints. The sciatic pains are relieved in from twenty-four to forty-eight hours. On only two occasions was an additional stretching (under anaesthesia) necessary. In early cases, there was a tendency in about 25 per cent. of the cases for the hamstrings to recontract, with occasional recurrence of sciatic pain. Since the procedure of forcibly stretching the affected limb daily, following operation was instituted there have been fewer relapses.

Inflammatory Cases.—Sciatica due to inflammations of the sacro-iliac joints, lumbosacral joints or lumbar vertebrae do not respond to this method of procedure, and account for a few failures. In fact, the symptoms are often aggravated by forcible stretching. The proper method of treating these patients consists of rest, support to the spine, removal of foci of infections, anti-rheumatic medications and local treatments, such as baking and high frequency currents with cataphoresis. Those failing to respond are best treated by ankylosing operations. The contra-indications to the manipulative treatment therefore are: (1) inflammation of the spine; (2) tuberculosis of the spine; (3) fractures or dislocations, and (4) tumors (cystic or malignant).

The danger of fracturing or dislocating the femur is overcome by stretching only in an anteroposterior plane, avoiding rotary force. Care should be taken to exclude such possibilities as cysts, tumors or osteoporotic diseases of the bones of the lower extremities and spine.

Attention must again be called to the possibility of traumatic palsies following stretching or manipulation. Two such instances have been observed.

The Indian Medical Service.

The Medical Press, August 5, 1925, p. 120.

THE EARL OF BIRKENHEAD, Secretary of State for India, said in reply to Lord Sydenham in the House of Lords on Thursday last, that the Indian Medical Service and its organisation had always been a matter of extreme difficulty. It was at the same time a military and a civil service and the interests of the two branches had not always been the same. The 1919 reforms had introduced further complications, and it must be made quite clear what were the obligations which were laid on the Government by the Government of India Act, and the statutory rules made under it. Generally speaking the civil medical administration in India included hospitals and public health, and the provision for medical education, and these were all transferred subjects, the responsibility for which rested with the provincial governments, and the Secretary of State had divested himself of the powers in regard to them which he formerly exercised. The Secretary of State would no longer undertake to recruit officers for the provincial civil medical administration in India, or in particular for the civil hospitals as such, nor could he assume responsibility for the medical care of British non-official residents in India. He had received recommendations from the Government of India on these matters and their consideration was well advanced in his department, but he was not yet in a position to indicate his final decision. He could, however, say that the Indian Medical Service would be retained. It would be essentially a military service, but officers would be lent to the civil administration. It was of the

first importance whether a service on these lines would attract recruits of the right class. He thought that the research and professional appointments which had always been one of the attractions of the Indian Medical Service would help in this respect. He was hopeful that a solution would be found on these lines which would appeal to the medical profession in Great Britain and Ireland.

Report of the Fourth Session of the Health Committee of the League of Nations held at Geneva, April 1925.

SOME very important work was put through during the eight sittings of the Committee. The following reports by officers and the special commissioners of the Committee were received and discussed:—

Report of Dr. Gilmour on Health Conditions in Persia.

Report of Dr. Haigh on Health Condition in Albania.

Revision of the International List of Causes of Death.

Report of the Opium Commission.

Report of the Commission on Instruction in Public Health.

Report of the Cancer Commission.

Abuses arising from the use of Patent Medicines.

Report on the work of the Far Eastern Commission.

Letters from Japanese and Dutch Governments regarding draft International Convention for the Far East.

Report of the Tuberculosis Commission.

Report of the Malaria Commission.

One of the most interesting innovations by the Health Committee has been the arrangement for interchange of visits of health officials between various countries. Two delegates from India will shortly visit Japan to study the Japanese system of public health work. In Europe a great number of interchange visits have already taken place.

The Committee endorsed the work of the Far Eastern Commission and agreed to establishment of the Singapore Bureau of Epidemiological Intelligence.

The report of the Malaria Commission showed a wide field of activity and will be reviewed separately. As a result of the work done by this Commission numerous applications for further assistance are being received from various Governments.

The Tuberculosis Commission is investigating the question of the alleged diminution of the disease and possible causes thereof. No reports are yet ready.

The Cancer Commission has collected a vast supply of data regarding incidence and malignancy of cancer by nationality or race, locality, civil state, age and natality. These data are to be statistically treated.

The work of the Health Committee is one of the most fruitful outcomes of the establishment of the League of Nations. The Committee is financed by a generous grant from the budget of the League and can maintain a body of whole time expert investigating officers and also provide funds for the expenses of commissions. Its value as a "liaison" office is immense.

Office Internationale D'Hygiene Publique Proces verbaux des Séances, October 1924.

THE sittings of the Permanent Committee of the Office Internationale are peculiar in that no resolutions are ever carried. The various subjects brought up are discussed and argued and when everyone who wishes has spoken the next subject is taken up. Therefore from the printed copy of the proceedings it is not always easy to find out what was the general sense of the meeting. The reviewer was present at this particular session. Replies to questions raised were read from various Governments concerning the adoption of a legal international standard for antisera such as anti-diphtheritic and antitetanic. All Governments agreed to accept an international standard but many (including

India) objected to the introduction of legislation on this point.

Replies to questionnaires regarding:—(1) A model Bill of Health for ships; (2) Treatment of sailors for venereal disease at foreign ports; (3) Possibilities of hæmatological examination of pregnant women for syphilis were read and recorded.

The second day was occupied in yet another discussion on the revision of the International Sanitary Convention of 1912. This Convention is long overdue for revision and the various articles have been under discussion for the past four years. Agreement is all but reached and it is hoped to hold an international conference of delegates from all signatory nations in November 1925.

On the fifth day a somewhat lively meeting took place in which the delegates from the British Dominions, India, Australia, Canada and South Africa took exception to the activities of the Health Committee of the League of Nations on which there is only one delegate from the whole British Empire. The discussion that took place showed that the Office Internationale had no intention of playing second fiddle.

Papers and discussions of great interest took place on:—(1) Rodents and their parasites. (2) The relation of pneumonic plague to bubonic plague and the recognition of a separate ætiology for the first named. (3). The incidence of tabes and general paralysis as influenced by modern treatment of syphilis. (4). Scarlet fever which for some cause is lessening in severity in most of its endemic homes except Italy where its virulence has increased.

Infantile mortality, rhinoscleroma, sleeping sickness and tuberculosis in Africa were debates of interest. A lively discussion took place as to whether 'alastrim' or white pox should be recognised as a separate entity. The Committee seemed evenly divided on this point.

Other discussions were on goitre in Switzerland and its relation to cancer of the thyroid, the treatment of leprosy and kala-azar.

The report is brimful of interesting debates by delegates of 55 nations. It is written in French.

Report of the Malaria Commission of the Health Organization of the League of Nations, Geneva, March 1925.

THIS report begins with a "Summary of Impressions of the Tour" for which the Commission as a whole accepts responsibility. The statements and opinions in the separate reports relating to the various countries visited are those of the particular authors who have written those reports.

The area dealt with may be described as South Eastern Europe extending from Italy on the west to the Volga region of Russia on the east.

The first conclusion arrived at is the necessity of making a distinction between the characteristics of endemic malaria and those of epidemic outbreaks. In India we have recognised this necessity long since for the ætiological factors governing such fulminant outbreaks as the Punjab epidemic of 1908 are entirely different from those governing endemic malaria in deltaic Bengal and the submontane valleys of India.

The Commission debates whether the policy shall be concentration of effort in the prevention of particular diseases or whether to devote attention to general hygiene—public health conditions such as housing and education. The Commission note that while malaria is no doubt a disease of great importance it is not always easy to decide what rank it takes among different causes of sickness and death. This is a problem of greatest importance in India. It has been openly said in the British Parliament that malaria causes 1½ million deaths a year in British India. Malarialogists in India have assumed that possibly one third of reported deaths are directly or indirectly due to malaria. In Bengal the reviewer accepted this figure and repeated it in 1911. It is pure hypothesis. There is little evidence available

and in view of increased knowledge of other causes of death, notably cholera, phthisis and kala-azar, compared with the few cases of fatal malaria seen in hospitals it is possible that this mortality is grossly overstated.

A truer estimation of mortality and morbidity from malaria in India is badly needed and consideration whether purely anti-malarial schemes are called for.

The Commission states that the following primary measures are indispensable:—

(a) The thorough treatment and after-treatment of all cases of malaria.

(b) The discovery and treatment of "carrier" cases by house to house and school inspection using spleen and blood examinations.

(c) Teach the inhabitants how to use mosquito nets and how to catch and kill those mosquitoes which find a resting place in houses.

The report says:—

"In view of the overwhelming importance of destroying domestic mosquitoes—that is to say, those which have gained access to living rooms which have had the opportunity of becoming infected and which will within a short period become the real and dangerous factors in spreading the infection—it would appear that along this line lies the simplest, most direct and perhaps also the easiest and least costly method of at least staying the malaria problem in rural areas."

This is the first time that the reviewer has seen anti-adult measures put in the front rank. In Panama it was considered a valuable accessory only. Increasing value given to this procedure is a feature of modern writers.

In addition the Commission emphasises that in certain limited and carefully selected areas conditions may be favourable for the adoption of measures directed against anopheles larvæ and anopheles adults in general. They do not recommend prophylactic issue of quinine except in carefully controlled conditions.

Of the individual monographs that of Professor Swellengrebel's is the most interesting and important.

Professor Swellengrebel in his report of Italy calls attention to the false idea held outside Italy of the nature of Italian "major bonification" schemes. Many of these the Italians had in operation before the connection of the mosquito with malaria was traced and they are all primarily designed for the creation of rich agricultural areas whereby the economic conditions were improved, the enhanced well-being reflecting favourably on the general resistance of the population to various diseases and to malaria in particular.

He writes of Italy:—

"We saw that even in well kept bonifications where malaria has been much reduced larvæ still abound in ditches (round Ferrara) and anophelism is not less; and that near bonifications where an intensified anti-larval campaign is being carried on anopheles abound in houses and stables (Ostia). The effect of small bonifications—as in Holland so in Italy—was practically nil, as a reducer of anophelism and the visit taught anew that the hygienic value of a bonificazione is identical with its economic value. The assertion is not true that Italy lays more and more stress on anti-larval measures to be performed on a large scale. This assertion if believed would lead to a deplorable waste of time, money and energy in other countries."

This opinion of Professor Swellengrebel's is fully endorsed by the Commission. (Section V "Measures of improvement," p. 59).

The opening paragraph of the 3rd section of the report on "Measures concerning Man" is as follows:— "Almost universally the Commission finds that the treatment of patients by quinine is the basis of the anti-malaria campaign; and justly so in view of the alternative, the long and costly effort called for to wage a really victorious anti-anopheles war."

The conclusions of the Committee represent the very latest views of European expert observers and the report needs most careful study by all malarialogists in India.

The principal measures advocated are quinine treatment of the infected sick combined with improved economic conditions whereby malaria ceases to be a widespread cause of mortality and morbidity and is reduced to the status of one of the minor ills to which flesh is heir.

Crippling due to Fractures.

In a lecture reported in the *British Medical Journal* of May 16th, 1925, Sir Robert Jones deals with the deplorable degree of crippling which so often results after the treatment of fractures. He attributes the failures to a lack of proper training in the handling of fractures and appeals for the establishment of special fracture clinics in all the teaching hospitals. He points to the vast improvements which took place in the handling of fractures in the later stages of the war, the mortality of the compound fractures of the femur having fallen from 80 per cent. in 1916 to 20 per cent. in 1918 owing chiefly to the early application of the Thomas splint. In other fractures greatly improved results were obtained by expert supervision, simplification of apparatus, team work, segregation and appropriate after-care.

He claims that similar improvements could be obtained in civil practice. His remarks on the common mistakes in dealing with fractures are so important that they are reproduced almost in full.

Common Mistakes.

Although an end-to-end apposition of a fracture is desirable, it is not essential to perfect function. Indeed, the ill effects following fractures are often due to injury to the soft parts, as may be instanced by ischaemic palsy and injuries to nerves. An end-to-end apposition with imperfect deflection of body weight is infinitely more serious than a slight overlapping, where body weight falls in correct line. In dealing with fractures of the shafts of long bones the first consideration, is to secure a true anatomical alignment of the bone, so that the axis of movement of the joints at the two ends of the bone may retain their correct relative positions. Many crippling deformities are due to a want of recognition of this fact.

Again, let us instance the femur. It is a common experience to find elderly persons, whom the hospitals were unable to treat, handicapped by the extreme disabilities which follow fracture of the neck of the femur. The limb is shortened, adducted, and rotated outwards, and yet quite a large proportion of such cases simply but properly treated would have resumed their useful citizenship. Abduction and inward rotation under extension would have secured in the limb a range of movement which would have more evenly distributed the pressure of the head in the acetabulum, while later a weight-bearing splint would have prevented the shortening. Again, how common a thing it is to meet with an old case of fracture of the upper third hobbling with a shortened and adducted limb, his body weight so deflected as to strain both hip and knee. By a simple manipulation and fixation this catastrophe could have been avoided. Or it may be a fracture of the middle of the femur with lateral or antero-posterior angulation, with which any practitioner could have dealt if his tuition had been effective. The lessons of the war should have impressed everyone with the knowledge that a femur in good alignment while recumbent would almost surely become crooked if walked upon without weight-bearing protection. Or take that most common and distressing deformity following a fracture of the lower third of the femur due to sagging at the seat of fracture, and resulting in a genu recurvatum. A piece of bandage used as a sling under the seat of fracture should easily prevent such a deformity.

Such deplorable results are frequently found. Every excuse but the right one is offered. A common one is *muscular spasm*. My experience in the treatment of fracture is that if muscles are sufficiently controlled they

come to rest and cease to struggle, but that if the control is inefficient or intermittent then reflex movements are active, and that all muscles enervated from the same region share more or less in the excitability. How commonly we see a knock-knee following a fracture of the lower third of the tibia. This is generally due to the common practice of setting a fracture of the tibia as if it were a straight bone; we place a pad on the inner side of the ankle in such a way as to obliterate the normal curve. But of all fractures which are badly managed that described by Percival Pott is the most common. A distinguished hospital surgeon, who looked after the London police, stated once that he had never known a police officer who had sustained a Pott's fracture return to his full duty. This statement is a notable testimony to the inefficiency of routine hospital treatment, for most of such fractures are taken direct to our teaching centres. As we all know, a Pott's fracture exhibits a dislocation backwards of the foot, together with eversion. We constantly find the unreduced dislocation as an end-result; yet this dislocation is never difficult to reduce provided the method has been taught. The reduction of the deformity should be undertaken at the earliest possible moment, although it can often be accomplished by manipulation at any time under three weeks. Every student should be taught that the knee should be fully fixed, the heel pulled forwards, and the lower end of the tibia simultaneously pushed backwards. The reduction is usually accompanied by a click, which is heard and felt as clearly as in the reduction of a dislocated shoulder. The foot should be fixed in inversion. Even if the bones are restored to their normal relationship eversion will recur later unless during standing and walking body weight is deflected to the outer side of the tarsus.

In the upper extremity, how common it is to find a stiff elbow following a fracture just above or through the joint, and this sometimes in spite of complete flexion. Failure to reduce the fracture accurately is generally the cause of this. It is not enough to take hold of the arm and merely to flex it. It should first of all be supinated, then extended and pulled, and while the upper end of the fracture is pushed back, the forearm should be pulled forwards and flexed. A student should be taught this manipulation, for it will save him many a serious disappointment. The application of the internal angular splint is happily becoming less frequent. It is a pernicious method. The advantage of the manipulation described is invaluable to the practitioner, for it is applicable to most fractures of the elbow, and indeed to dislocations also.

Avoidable Complications.

The growing tendency of the immediate application of plaster-of-Paris assumes the immediate and complete reduction of a fracture, which is not always possible. It prevents the intelligent use of pads, and does not allow of inspection and supervision. Unless applied by an expert it often tends to interfere with the vitality of the limb because of circular compression. If put on a limb newly injured it will become slack as soon as the swelling subsides. It does not permit of massage, so often necessary to hasten recovery. In spite of this, circumstances may arise where the application of plaster is the only available procedure. No student should be allowed to leave his hospital until he is familiar with the modern methods of applying plaster. A badly applied plaster often proves a very dangerous splint, and is a common cause of non-union and of pressure sores.

The student is not sufficiently warned against the pressure slough, nor the best ways of avoiding it. A slough may occur in twelve hours or less if plaster is placed over a thinly clad bone, and while developing give rise to nothing more than discomfort. Deep sloughs occur without any complaint having been made by the patient. This type, which occurs without pain, is generally the worst, the pressure over bone having benumbed the skin from the first. If, therefore, it becomes imperative to employ pads on such places they should

Nov., 1925.]

be examined and changed frequently, despite the fact that the patient may be feeling very comfortable.

Granted a fair apposition, non-union rarely occurs. It is generally the result of nervousness and impatience. Some surgeons are never content unless they worry the fractured ends week after week to see how consolidation proceeds. Such procedure is as unscientific as the action of a cook who opens her oven door every five minutes to see how the hot-pot progresses. Until the normal period of completion of consolidation, absolute rest should be ensured. A fracture of the shaft of the tibia may take many months to unite.

After-treatment and Protection.

The student is not taught the length of time restraint should be continued nor the nature of after-care. Even to-day, text books do not instruct him as to when he may reasonably expect complete consolidation. The result is that a patient may leave a surgeon with a limb of normal form and length, and in a few weeks it may be short and crooked. It cannot be too clearly emphasized that a lower limb which can pass the test of a manual examination may completely fail when body weight is superimposed. Adequate protection should therefore, always be given to a fractured limb when walking is prescribed. In spite of a well equipped physiotherapy department attached to the hospital, how few students are able to give intelligent instruction to a masseuse, or to direct a gymnast in treating a deformity, or show an electrotherapist the muscles he should stimulate in order to overcome weakness. The instruction generally given is, "Have your arm massaged," or "Use the faradic current," or "Give exercises to this man." We blame the physiotherapists if they do not carry out the doctor's instructions; we do not dwell on the fact that the doctors—with few exceptions—do not possess the knowledge to instruct. Surely there is something radically wrong with a syllabus which leaves the students ignorant in matters of such practical importance. It is an open invitation to every species of quack.

How few students have been taught to distinguish between a joint which may be moved and one which should be kept at rest—and how many bitter disappointments result from this. How few men know how to handle a fracture; how to hold the broken arm with a *minimum of pain*; how to feel for crepitation; how to avoid muscular spasm; how to reduce deformity, and, as it has been called, "set" the fracture. A surgeon, who is interested in his subject, and knows it, will teach the student more by demonstrating one case than can ever be learnt by the student in personally handling twenty cases in a spirit of adventure. The student should be taught to use his eyes, his measuring tape, and the art of reducing a fracture almost painlessly by postural muscle relaxation. Such an education in manipulation is worth any amount of untutored experience. The rough handling of fractures by the unskilful is an outrage on a patient, and when done in the presence of a student is an extremely bad example. A malunited fracture cannot be cured merely by an operation; all the operation can do, is to reconstruct the fracture, and a satisfactory result can only occur by the maintenance of the alignment until consolidation of the bone is complete.

The Choice of Splints.

Sir Robert emphasized the urgent necessity there is for each hospital to scrap its useless splints and retain for teaching purposes only those of known efficiency. Hospital staffs should, from time to time, meet and select the most useful—and they are generally the simplest—splints, and no students should graduate unless he has completely mastered their correct application. Furthermore, in order to simplify the training and to stabilize the examination of the students, this idea could be extended by the formation of a committee, representative of all teaching hospitals, to decide upon the best type of splints.

The Decline of Litholapaxy.

By ALFRED HOOTON, C.I.E., M.R.C.S., L.R.C.P.
British Med. J., April 11th, 1925, p. 690.

GENERAL HOOTON protests against the tendency to regard litholapaxy as an obsolete operation.

The chief arguments now brought against it appear to be that suprapubic lithotomy can be done with nearly as great safety, that litholapaxy is difficult to learn and dangerous when performed by inexperienced operators, and that there are more recurrences after it than after lithotomy.

The impression is widely prevalent in India, that litholapaxy in skilled hands is much the less dangerous operation and our figures speak for themselves, and still more emphatically if it is admitted, as we all contend, that, contrary to the impression at home, our cases on the average are far less promising than those which come to the English hospitals. We have a very large proportion of large stones and septic bladders to deal with, and we consider, moreover, that the idea which seems to prevail at home that Indian patients in general bear operation better than Europeans is entirely erroneous. It remains to be said that suprapubic lithotomy is not without its dangers.

The frequency of recurrence after litholapaxy is much exaggerated. Under proper conditions recurrences should be very rare. A fair test of the general result of the operation is its reputation with the public. The Indian cultivator, who furnishes the great majority of our up-country patients, is an acute judge of the practical results of surgery, as shown, for instance, in his appreciation of Bassini's operation for hernia. As regards litholapaxy, he made up his mind long ago, and there is no surer way of emptying one's hospital than by reverting to a cutting operation where crushing has formerly been in vogue. There is not only the escape from the knife but the early discharge from hospital to be considered, and it is, of course, quite common for children who have been relieved of small stones by the lithotrite in the morning to be running about in the afternoon. It is the opinion of an overwhelming majority of Indian surgeons that litholapaxy in proper hands has great advantages over any of the cutting operations in all but a small percentage of complicated cases, and it would be a very great pity if the contrary view were to be generally accepted and taught in the British schools, particularly in the case of men who are destined to practise in the East. A list of cases treated in four representative hospitals of this Presidency is afforded. Two of these are reproduced.

I.—Cases operated on by Lieutenant-Colonel R. W. Anthony, F.R.C.S.I., during three years and three months in 1920-23 at the Civil Hospital at Hyderabad, Sind.

Cases. Deaths.

Litholapaxy (including 30 perineal litholapaxies)	..	1,253	7*
Suprapubic lithotomy	..	11	3
Perineal lithotomy	..	0	0

* Three others "discharged otherwise"—probably died.

This is the most noted centre for vesical calculus in this Presidency, and has dealt with an average of 464 cases a year during the last ten years. Colonel Anthony says that he looks on every case of stone as one for litholapaxy if it can be done, and that there are very few cases in which it cannot, given an experienced operator. If it is impossible to crush by the urethra in the ordinary way he performs perineal litholapaxy. He crushes stones up to about 6 ounces, and hardly ever gets one that he cannot deal with, either by the ordinary on perineal route, by means of a large lithotrite or a hammer. He apparently never does perineal lithotomy now, and only performs suprapubic lithotomy primarily from choice in patients with enlarged prostates. Thus, as he points out, his suprapubic cases must be taken largely as failed litholapaxies of a complicated nature—for example, cases in which the bladder has an hour-glass shape, or processes like the finger of a glove containing stone, or encysted stone; or those rare accidents

where the lithotrite has jammed, or perforation of the bladder has accidentally occurred.

II.—Cases operated on by Lieutenant-Colonel T. S. Novis, F.R.C.S., at the Jamsetjee Jeejeebhoy Hospital, Bombay, from June 14th, 1920, to December 31st, 1923.

	Cases.	Deaths.
Litholapaxy	114	1
Perineal litholapaxy	0	0
Suprapubic lithotomy	17	5
Perineal lithotomy	2	0

Note.—Of the deaths from suprapubic lithotomy, two were complicated with prostatectomy, and two developed pneumonia.

This is the chief general hospital in Bombay, and associated with the Grant Medical College. Here, also, litholapaxy is the routine operation, the contraindications quoted by Colonel Novis being very large or very hard stones, very soft putty-like stones, stricture, enlarged prostate, extensive kidney disease, and bladder growth of any considerable size. He lays stress on a routine cystoscopic examination of the bladder, both before operation, to exclude the possibility of encystment of the stone or other complications, and immediately after, or at any rate before discharge, to make sure no fragment is left behind. The series quoted includes two cases of hæmorrhage, in both of which suprapubic cystotomy had to be performed, and in one an extraperitoneal rupture was found to exist. Both these recovered. Here also the suprapubic cases are the worst and cannot be quoted for purposes of comparison.

A Method of Treating Infected Ulcers.

By S. A. PFANNENSTILL, M.D.,

Late Chief Physician of the Municipal Hospital, Malmö, Sweden.

Brit. Med. J., April 18th, 1925, p. 732.

In the case of an ulcer on the surface of the body or the limbs sodium iodide is given in an average dose of 15 grains two or three times a day. Larger doses may be given, 60 to 90 grains a day, the effect of the treatment then being greater; but this entails some risk of iodism. Immediately after the first dose of sodium iodide the local peroxide treatment begins. The ulcer is covered by a layer of cotton-wool, not too thick, which is kept continually soaked with the peroxide solution dropping from a dropping-phial every tenth or fifteenth minute, or even more frequently. The more thoroughly the wool is soaked with peroxide the greater is the effect obtained. The strength of the peroxide solution must be kept at 1 to 3 per cent., generally 1 to 1½ per cent., because stronger solutions often irritate the sound skin around the ulcer. An addition of ¼ to ½ per cent. acetic acid will prove quite sufficient for acidifying.

Since the blood contains most sodium iodide about one to two hours after its administration, special attention should be devoted during that time to the thorough soaking of the ulcer with peroxide solution. After the last dose of sodium iodide has been given for the day the local treatment of the ulcer should be continued for at least three to four hours in order to make full use of the iodide which is still circulating in the blood and will be gradually excreted by the kidneys.

When the ulcer has invaded the deeper tissue layers, forming pockets, it is necessary to tampon the pockets loosely with gauze in order to bring the infected walls of the ulcer into intimate contact with the peroxide solution dripped on the gauze. Infected cavities in bones and joints are to be treated in the same manner. *Fistulæ*, however, usually cannot be directly treated, it being difficult, or even impossible, to conduct the peroxide solution in sufficient quantity through the narrow ducts. It cannot be repeated too often or too strongly emphasized that the efficiency of the method depends upon there being an intimate and prolonged contact between fresh hydrogen peroxide and the infected surface to which sodium iodide is being carried through the

blood vessels. A surgical operation will sometimes make a *fistulæ* suitable for this treatment.

For treating ulcerations in the nose the nasal cavity must be loosely plugged with gauze upon which the peroxide solution must be dripped as before indicated, care being taken that the patient's head is held back so as to enable the liquid to flow up into the nose. In treatment of affections in the mouth and throat the method of applying the peroxide solution must be changed. In the case of the mouth it is usually sufficient to rinse it frequently with peroxide at intervals of a quarter of an hour or less. For treating the throat a spray apparatus is necessary; different types are on the market, some being driven by compressed air. When hydrogen peroxide is being used for treatment of affections in the mouth and throat it must be remembered that it is impermissible to make the solution acid with the common acids, lest the teeth should be injured. The only acid suitable is boric acid, this being inoffensive to the teeth and quite effective in a 1 per cent. dilution.

The efficiency of this method of treatment is due to the antiseptic agent, iodine, being generated in the nascent state locally; it operates at a deeper level in the infected tissues than do other antiseptics, the iodine being generated not only on the surface but also at some depth under it.

The method has been employed in common infected ulcers and tuberculous ulcers, but since its application is less convenient than the usual methods of treatment it should be reserved for serious cases, in which these latter methods are less efficacious, such as phagedænic chancre and infection in open joints and bones. The method has proved very valuable in treating infectious conditions and ulcerations in the mouth and pharynx, such as mercury stomatitis, pyorrhœa, gingivitis, and angina necrotica (Vincenti).

The method has been frequently employed in treating tuberculous and lupoid ulcerations in the nose and throat, but with variable results.

Only in the case of superficial tuberculous ulcers can a thorough and permanent cure be expected; with deeper infections no lasting cure is to be obtained. For tuberculous and lupoid ulcers a complete and lasting cure can be obtained if the infection has not penetrated too far into the tissues, but if the infection is deep, as is commonly the case, only a superficial healing, or none at all, is to be expected.

The Treatment of Tropical Ulcers.

It is well known that external ulcers are very numerous and difficult to cure in the tropics. Not only are there those ulcers which commonly occur in temperate climates and which, owing to unfavourable tropical conditions, progress unfavourably, but also there are ulcers which are indigenous. The method should be particularly useful in the treatment of these tropical ulcers.

Reviews.

SURGICAL PATHOLOGY.—By William Boyd, M.D., M.R.C.P. (Edn.), F.R.C.S. Philadelphia and London: W. B. Saunders & Co. Pp. 837, with 349 illustrations and 13 coloured plates. Price, 45s. net.

THIS is a new book on surgical pathology. Many books have been written on the subject but it is a branch of pathology which has not received the best attention from writers and there is certainly room for another good book on the subject. Books on general pathology must of course cover the ground that is covered by this book but writers do not always deal with the subject from the view-point of the surgeon. A sound knowledge of anatomy is important to the surgeon but a sound knowledge of pathology is essential otherwise he "is no better than a heaver of flesh and a drawer of blood."

The chapter on surgical bacteriology is surprisingly short but one soon realises that the writer has confined

himself strictly to the subject as it affects the surgeon; this to a large extent consists of a description of the methods of collecting material. Perhaps a note on the intelligent interpretation of pathological reports might have been included here.

There is a short but very explicit note on blood grouping. A number of chapters on general pathology, on inflammation, healing, gangrene and the more important specific infections, follow. A short but complete review of the research in the causation of cancer that has been carried out during the last few years is given; this naturally does not include the recent work of Dr. W. E. Gye as the book was published before this appeared. The rest of the book is devoted to regional pathology. The book is a complete one. It is a great advance on any book on the subject with which the reviewer is familiar. The literary style is a pleasant one. There are 349 very clear text illustrations and 14 beautifully executed coloured plates.

The type is large and clear and the paper is of good quality.

DISEASES OF THE GUMS AND ORAL MUCOUS MEMBRANE.—By Sir Kenneth Goadby, K.B.E. Second Edition. London: Humphrey Milford. Oxford University Press. Pp. 408. Price, 42s. net.

THE first edition of this book was published in 1923. The fact that a second edition is already demanded is sufficient evidence of the importance of the subject and is a great tribute to the author and the publishers.

The mouth is the ground on which many branches of medical science meet; the physician, the surgeon, the dental surgeon, the pediatrician and the bacteriologist all have an interest therein, so that a book of this nature has a wide range of readers.

In the chapters on "disease originating from mouth infections" and "disease with oral symptoms" the author shows discrimination and restraint. It would have been easy to have distributed the subject-matter of a text-book of medicine between these two chapters. Pyorrhæa alveolaris has at various times been held responsible for most diseases and such diseases as have not been associated with this condition have at least some mouth complications.

The new departures in this edition include a section on the "poisoned heart" in the chapter on diseases originating in mouth affections and a chapter on vaccine therapy in connection with infections of the mouth. The former section is illustrated by a number of electrocardiograms. The chapter on vaccine therapy is written for the student, for the physician or dental surgeon and for the bacteriologist; it includes a general discussion on vaccine therapy, a description of the methods of obtaining bacterial samples for the preparation of the vaccine, a discussion on various kinds of vaccine and the selection of the organism and finally suggestions as to the administration of the vaccine.

The book is illustrated with a number of good text figures and 8 well executed full-sized coloured plates. We can thoroughly recommend the book.

MINOR SURGERY.—By L. R. FIFIELD, F.R.C.S. (Eng.). London: H. K. Lewis & Co., Ltd., 1925. Pp. X plus 491, with 273 illustrations. Price, 12s. 6d. net.

Those who perform minor surgical operations must do them well as patients demand a good result for what they regard, often quite wrongly, as trivial undertakings.

The greater part of minor surgery comes within the province of the general practitioner and it is essential for him to proceed on correct lines as small errors loom large and mean the loss of reputation and practice.

This book covers the whole subject and is written by one who has a large experience in the teaching of students.

The chapters dealing with infection of the hand, fractures and minor surgical operations are very full and useful.

It is altogether an excellent book admirably suited as a ready reference for students and general practitioners.

KOBY'S SLIT-LAMP MICROSCOPY OF THE LIVING EYE.—Translated by C. Goulden, O.B.E., F.R.C.S. and Clara Lomas Harris, M.B. London: J. & A. Churchill, 1925. Pp. 221, with 43 illustrations. Price, 10s. 6d. net.

THIS excellent manual on the use of the slit-lamp is the work of the first assistant at Professor Vogt's clinic at Basle, where the ophthalmologists of all the world have gone for instruction in the use of this highly interesting new instrument, and is a summary of the teaching given there in the last two years, and supplementary to Professor Vogt's "Atlas of the Microscopy of the Living Eye."

It is essentially practical in character, the first three chapters being devoted to the description of the instrument and general methods of using it, and after that come chapters on the conjunctiva, cornea, anterior chamber, iris, lense and vitreous, giving in each case the special technic for examining the structures, and describing the normal and pathological appearances commonly found in them. This is interesting to all ophthalmologists and not merely to those who have access to a slit-lamp, as it will enable them to see more and interpret better what they see when using the ordinary methods of focal illumination; especially if they have studied Harrison Butler's recent papers describing what can be seen when using an ordinary nitrogen 2-watt lamp as the source of illumination.

The illustrations are not numerous but very useful and practical, and the general turn-out of the book is good.

PEDIATRICS.—By various authors. Edited by Isaac A. Abt., M.D. Vol. VI. Philadelphia and London: W. B. Saunders Co. Pp. 736, with 150 illustrations. Price, 45s. net.

THE sixth volume of this great system of pediatrics follows the same lines as the preceding volumes. It deals chiefly with the infectious diseases of childhood, and with anesthesia in children. Each of the twenty-six contributors is a distinguished American physician or surgeon. The chapters on typhus fever and cholera are by Dr. Victor Heiser. The chapter on incubation and tracheotomy is particularly full and instructive and is very fully illustrated. Coloured plates of the eruptions seen in the exanthemata would have been valuable additions. The volume will be found indispensable to the specialist in children's diseases and will doubtless be acquired by every large medical library.

CHRONIC DISEASE: A WORKING HYPOTHESIS.—By E. Bach, M.B., B.S., D.P.H., and C. E. Wheeler, M.D., B.S., B.Sc. London: H. K. Lewis & Co., Ltd., 1925. Pp. VIII plus 153. Cr. 8vo. Price, 7s. 6d. net.

THE authors set before them the task of pointing out how intestinal toxæmias are associated with a constipating diet and claim that uncooked food, comprising raw fruit, nuts, vegetables salads, dairy produce, wholemeal bread, cereals and milk puddings will change the physical and bacteriological characters of the faeces so that the non-lactose fermenting organisms and the toxic substances which form part of the intestinal contents gradually disappear. The authors hold that the presence of these poisons combined with increased permeability of the bowel wall to toxins produce a cumulative effect and that meat eaters sooner or later begin to suffer from the effects of the intoxication. One line of attack on the poison-producing organisms is by vaccine treatment which the authors claim to have caused striking improvement in many cases. Instead of regarding local infections as being the causes of arthritis and fibrositis, they claim that in many cases the local infections become possible owing to the absorption over long periods of intestinal poisons. The good effects of vaccine treatment are regarded as being proof that there is a specific as

well as a general resistance to chronic infections. Even in a large proportion of cases of cancer the treatment of the authors has diminished pain and apparently prolonged life, but no case of cure is claimed.

The treatment recommended by the authors consists in a diet on the lines already mentioned, combined with vaccines made from faecal organisms cultured on neutral red-bile salt-peptone-lactose agar. Usually there is only one kind of non-lactose fermenting organism, if there are two kinds both are used in preparing the vaccine. Cultures are made on agar slopes kept at 37 degrees centigrade for 16 hours. The growth is mixed with saline and killed at 60 degrees centigrade. The growth of one average sized slope is made up to 25 c.c. and 25 c.c. of a mixture of one part of distilled lysol with three parts of absolute alcohol is added. The doses of the vaccine range from initial doses of 0.04 to 0.9 c.c. the dose being approximately doubled on each occasion unless marked local or general reaction follows, in which case the next dose is not increased. The interval between the doses is usually long the subsequent dose is not given until improvement ceases to take place. An analysis of 500 cases is given from which it appears that excellent results were obtained in the majority of cases of anaemia, chronic rheumatism, neurasthenia, chronic gastritis and chronic colitis. Good results are claimed in a fairly large proportion of cases of rheumatoid arthritis, sciatica, neuritis, epilepsy, chronic headache, etc. Altogether the book is well worthy of study although it cannot be claimed that it offers a complete solution of the problem of chronic intestinal intoxication and its multifarious after-effects.

ARTERIOSCLEROSIS.—By the late Rt. Hon. Sir T. Clifford Allbutt, P.C., K.C.B., M.A., M.D. London: Macmillan & Co., Ltd., 1925. Pp. 108. Price, 5s. net.

THOUGH Sir Clifford had reached an advanced age before his sudden death, this little book shows no sign of senility on the part of its author; throughout its pages there is a freshness of outlook combined with mature experience and it is evident that Sir Clifford continued to be a student till his last days. Many of his views on arteriosclerosis have become part and parcel of our common knowledge and practice, but advances have been made in recent years by other workers and by the author himself so that this volume forms a necessary supplement to his great work on diseases of the arteries which was published in 1915. Not the least valuable feature of the book is its small size, it forms an enlarged edition of a post-graduate lecture, and so the busy practitioner will find it possible to acquire the most recent views of the master in a very short time. The distinction between hyperpiesia and the hyperpiesis which is secondary to renal disease is clearly brought out, and though much remains obscure as to the causation of high blood pressure the practitioner who reads this little book will not fail to obtain clearer and more helpful views on the condition.

The line of treatment which is recommended is confessed to be purely symptomatic, it cannot be otherwise as the essential causes of high blood pressure remain uncertain. None the less the medical man will obtain great help from the chapter on treatment, which includes an account of the valuable aid which may be obtained from diathermy. It is characteristic of the energy and optimism of the author that he contemplated publishing full case reports on a later opportunity which unfortunately was not granted to him.

SYMPTOMS OF VISCERAL DISEASE.—By F. M. Pottenger, A.M., M.D., LL.D., F.A.C.P. Third Edition. St. Louis: The C. V. Mosby Co., 1925. Pp. 394, with 86 text illustrations and 10 colour plates. Price, \$6.50.

We can recommend this book to the clinician who wishes, in the short time at his disposal, to keep

abreast of modern advances in the basal sciences of medicine:—physics, chemistry, anatomy, physiology, etc., in their intimate relationship with clinical diagnosis and treatment.

The work is a compilation, but much originality is shown in the fitting together of theories and the unification of general principles.

In the introduction a plea is made for the study of the patient as an individual and emancipation of the clinical view of the patient from the thralldom of laboratory findings. In his opinion all possible use of the laboratory should be made, but the clinical study of the patient as an individual is the most important in making the diagnosis. Whatever the local bacteriological or pathological findings, the fact should always be kept in mind that the patient, both physically and psychically, is a complete entity, and any pathological process, wherever it may be, acts and reacts throughout the whole. It is the well-trained clinician who is able to detect these departures from the normal, long before the laboratory can show that anything is wrong.

The book proper is divided into three parts. In the first the vegetative nervous system is dealt with in its general, anatomical, physiological, pharmacological and physical aspects. In the second the relationship between the vegetative nervous system and the symptoms of visceral disease is shown. In proceeding to do this the author propounds a more or less new method of classification of the symptoms of disease. A brief quotation will best illustrate the method in which he goes about this:—"Many classifications of symptoms may be offered, depending on the point of view of the author, but a rational classification of the symptoms of visceral disease must take into consideration the colloidal state and ionic content of its body cells, the nervous and endocrine systems through which cellular activity may be influenced, and the psychic state of the patient." In the third part the question is dealt with regionally; the gastro-intestinal tract, the respiratory system, and the circulatory system are dealt with serially; then the salivary glands, the nasal and other mucosa, the larynx, the eyes, the urogenital tract and the subdermal musculature. Lastly we have a chapter on the innervation of the endocrine glands.

The book has some 86 illustrations and 10 coloured plates; it is written in a clear style and may be understood by anyone who takes the trouble to read it carefully. It is full of useful information and there are few who will not find its teaching most stimulating and enlightening.

EFFICIENCY TESTS FOR THE LIVER AND KIDNEYS. (LORD REAY LECTURES, 1923-24.)—Delivered by Sohrab H. Nanavutty, B.Sc., M.B., B.S., B.Hy. Bombay: Published by the Lord Reay Lectureship Endowment Fund, 1924. Pp. 35.

THIS useful little hand-book, dealing with the various tests for determining the liver and kidney functions, was the subject-matter of Lord Reay's lectures delivered by the author in Bombay in 1923-24. The author has dealt with the various efficiency tests for the liver and kidneys in a clear and concise way, both theoretically and practically.

We recommend this small book to both clinicians and laboratory workers who will, we are sure, derive benefit from its perusal.

THEORY AND PRACTICE OF NURSING.—By M. A. Gullan. Second Edition, with three additional chapters. London: H. K. Lewis & Co., Ltd., 1925. Demy 8vo. Pp. XVI plus 234. Price, 9s. net.

THIS is an excellent hand-book by one who knows her subject thoroughly and who also knows how to convey her knowledge to others. It will be especially valuable to those who give courses of instruction to nurses, especially if they use the book in the manner suggested by the author. The intention is that the summaries of instruction should be used as a basis on which the teacher should build her own teaching.

To nurses the book will be equally valuable, it contains in a readable form a precis of what every nurse ought to know. The author apologises for the free use of technical terms and it must be admitted that some of these are likely to remain mere words to the average nurse; on the other hand it is true that nurses like doctors take a professional pride in the use of large words which are incomprehensible to the lay man. We would even venture to commend the book to medical men who too often are unfamiliar with the important little details which can safely be left to the trained hospital nurse, but which have to be carried out by the doctor himself in places where qualified nurses are not available. It should be stated that the author is the Sister Tutor of St. Thomas's Hospital where an exceedingly high standard of nursing is maintained.

OPHTHALMIC NURSING.—By Mary Mason Spring-gay. London: Methuen & Co., Ltd. Pp. 133, with 67 illustrations. Price 5s. net.

This small book, written by the Matron of the Western Ophthalmic Hospital, London, describes the nursing technic taught in that hospital during the last 14 years, and, in addition to nursing details, gives a short description of the simpler diseases of the eye and complications which a nurse is likely to come in touch with, and a very useful account of the sterilisation and care of eye instruments, and the arrangements necessary for the ordinary ophthalmic operation.

The preparation of the patient for operation both as regards cleanliness and from a psychical point of view is well put.

The book is one which will be found very useful for nurses starting duty in ophthalmic wards, but the technic now in use in any of the larger Indian eye hospitals is more complicated and differs in many important details from that described here. The book, however, is well and clearly written and will be found very helpful.

Correspondence.

INDIAN DIETS IN RELATIONSHIP TO HEALTH AND DISEASE.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—In Majors Acton and Chopra's paper about the Tridosh theory of Ayurved in the July number of the *Indian Medical Gazette* there appeared the following statement:—"Pittya is anabolic and kaphya is katabolic, and pittya is heating and kaphya cooling." There appears to be some confusion as the following will show:—

The Tridosh theory is the basic principle in every department of Ayurved in health and disease.

Normal (physiological) pittya stimulates cellular activity, produces increased body heat and is katabolic or destructive in health. Similarly normal kaphya does not stimulate cell activity, produces no extra body heat and is anabolic or constructive.

In pathological conditions both abnormal pittya and kaphya dysfunction. There may be either hyper- or hypo-function.

In pittya hyperfunction, as in fever for example, there is further increase of cellular activity than normal, more production of body heat (fever) and increased katabolism or burning of tissues.

In pittya hypofunction, as in asthenic conditions (e.g., convalescence after fever, a stage described in the Unani system as neither health nor disease) there is reduced cell activity, reduced katabolism and reduced production of heat.

In kaphya hypofunction, as in constipation (one of the functions of kaphya is secretion and excretion) there is less anabolism, less cooling effect on the body and diminished secretion.

In kaphya hyperfunction, as in diarrhoea, there is increased secretion, increased katabolism or tissue waste but no increased cellular activity and no increased production of heat.—Yours, etc.,

HAZARIBAGH,
23rd July 1925.

CASES FOR DIAGNOSIS.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—In your issue for July two interesting cases are noted in both of which the diagnosis is in doubt. May I make the following suggestions in order to further discussion and obtain help?

The first case, reported by N. Chatterjee, M.B., seems to me very like Henoch's purpura.

This syndrome is reserved for those cases of purpura which are associated with gastric crisis. It is most common in boys about the age mentioned, i.e., 15 years. Vomiting is an early symptom and either diarrhoea or obstruction occur. Many cases have been operated on for intussusception or appendicitis. The temperature is never high, sometimes normal, thereby excluding purpura associated with small-pox or measles. General body pains especially arthritic are usually present.

Fatal results are usually due to cerebral hæmorrhage. The "subdermal hæmorrhages in the legs and abdomen" would fit in with the purpuric eruptions.

Personally I have never seen a fatal case of Henoch's purpura but those I have seen fit in well with the condition described. Transfusion is said to offer the best chance of recovery.

The second case reported by S. D. Narain, L.M.P., is of a man aged 42 with extensive burns, which had all healed except for a small ulcer. As the diagnosis of uræmia presents some difficulties I submit two alternatives.

Could the ulcer have become infected with tetanus and were the convulsions of this character? The classical opisthotonos is by no means always present and unless one is on the lookout for tetanus, it is very easy to miss atypical cases.

The second alternative is Stokes-Adams' disease. Possibly the original loss of consciousness might have been due to this and not to the coal fire. The rest in bed for several months might have diminished the symptoms temporarily while the absorption of toxins from the burns would be deleterious to the heart muscle.

When the impulse failed to penetrate the bundle of His and the ventricles stopped, the patient became unconscious; when the ventricles resumed and the pulse returned, convulsions occurred. Nausea and vomiting would fit in with the picture. Palpitation would be stimulated by the rapid contractions of the auricles contrasted with the slowly beating ventricles. Pulsation in the neck is also prominent.

With regard to treatment, caffeine and strychnine act well but digitalis is contraindicated as it reduces the conductivity of the bundle. A Wassermann reaction should be tried in every case.—Yours, etc.,

I. NEIL LEITCH, M.B., B.S. (Lond.),

MEDICAL RELIEF AND MEDICAL EDUCATION PROBLEMS IN BENGAL.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—The following is a copy of letter No. 260 dated the 25th July 1925 from the All-India Medical Licentiates' Association, Bengal, to the Surgeon-General with the Government of Bengal.

"I am under instruction of my Committee to request the favour of your kindly placing before the Government of Bengal the views of my Committee on the

burning question of medical relief and medical education in Bengal, which is evidently agitating the public minds at present, and all forces are mobilised and no stone is left unturned to carry the scheme into practical operation.

The Association and my Committee, I beg to submit, have already chronicled its opinion on this important subject in all its bearings, and communicated to you their considered decision in due course. They have opposed tooth and nail any measure, which, instead of doing any tangible good to the country and its people, would inflict a severe blow at the root of higher education in our medical schools, lower its standard and manufacture a lowly type of medical practitioner, who will work havoc when he is let loose with a cheap and inferior diploma in the midst of a poor, illiterate, suffering mass in the guise of a "legalised quack" which the benevolent Medical Act and the Medical Degrees Act intended to suppress.

My Committee desires me to go back to the history of two of the most useful classes of practitioners in India, which arose from humble types known not so long ago as "black doctors" and as "apothecaries." During the existence of this progressive class of licensed medical practitioners for three-fourths of a century the tendency has ever been upwards, and to the intense regret and surprise of my Committee a contrary tide has set in, and it is now vehemently urged to found a "network" of medical workshops and to create a lowly type of practitioner, for rural areas, where, in the opinion of my Committee, only a capable and efficient general practitioner, possessing a thorough knowledge in all branches of the science to deal with all classes of medical and surgical cases is called for, when it is obviously true that like the cities and towns the poor villagers are exposed to all sorts of maladies, and the great majority of the rural population have neither money nor mind nor any opportunity to avail themselves of highly qualified specialists and medical practitioners not living in their neighbourhood.

My Committee further begs to point out the new circumstance created in the country by the recent events, viz., (1) refusal of recognition of the M. B. degree of the Calcutta University by the General Council of Medical Registration and Education of the United Kingdom, (2) opening of Ayurvedic Colleges and schools, under the patronage of various Local Self-Governing Bodies and (3) the prevailing tendency of the "Intelligentsia" to resuscitate the indigenous systems of treatment, viz., (a) Ayurveda and (b) Yunani.

Over and above, my Committee has not failed to keep an eye over the number and quality of the students flocking to the gates of the medical schools in thousands to take up a career in medicine—considerably out of proportion to the vacancies in each school. Besides, at least, it is not within the knowledge and experience of my Committee that there has ever been a single prayer from the students, their parents and guardians, or the products of these institutions to lower the standard of medical education in our schools or deny the country the benefit of higher medical education and better medical aid.

My Committee fully recognises the need for increased medical aid for rural populations, for which a few medical schools and colleges should be founded, but my Committee is not inclined to sacrifice quality for quantity, particularly in the domain of "healing art" which deals with life, or prescribe a distinctly inferior type of "recipe" for the poor and unfortunate dumb population. This differential treatment between suffering man and man is galling to the taste of my Committee, and it is a wonder of all wonders how such a retrograde measure obtains support at the hands of my leading and educated countrymen whose hearts profusely bleed for the well-being of the poverty-stricken ignorant masses.

Although my Committee, I beg leave to add, never contemplates the idea of depreciating the value of curative lines of treatment, it would concentrate the energy

of the whole country for preventive measures, and preservation of natural immunity which is at bay owing to the acute economic distress prevailing in the country. The amount which is being collected for opening ill-equipped, poorly staffed and rickety hospitals, dispensaries and schools may better be employed for ridding the villages of their insanitary conditions and providing adequate and wholesome food, water and cloth to the famished people, who are unable to stand the numerous preventable diseases to which they prematurely succumb.

It goes without saying that the Association has recommended the extension of the period of study for our medical schools from four to five years, the abolition of at least the lowest grade of medical practitioners, i.e., the licentiates, and advocated the cheapening of "medicament" by manufacturing cheap medicinal preparations, accessories and appliances, which will prove conducive to the welfare of the distressed because my Committee agrees with the valuable Flexner report (United States) "that no physician poorly equipped or well-equipped will go anywhere where a livelihood cannot be gained" and as by cheapening the lawyers the litigations have not been reduced to the minimum but, on the contrary, the morale and capacity of the people have dwindled, by cheapening the doctor only without cheapening the paraphernalia and altering the economic conditions the salvation will not be forthcoming.

Taking all these points into consideration, my Committee begs to suggest that a strong Committee consisting of officials and non-officials of leading positions and enjoying public confidence, in which our Association should be represented, be immediately appointed for an open and exhaustive enquiry into the whole question, which affects millions of people in rural tracts, and my Committee fervently hopes that in the meantime there should be a cry of "halt" and all proposals to start fresh medical schools be postponed *sine die*.—Yours, etc.,

SATKARI GANGULI,

Provincial Secretary to the All-India Medical Licentiates' Association, Bengal.

30/11/25, DOCTOR LANE,
CALCUTTA,
29th August 1925.

THE BRITISH SOCIAL HYGIENE COUNCIL.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR.—We desire to draw attention to the first Annual Meeting of the British Social Hygiene Council which is being held to-morrow, and to the national importance of the subject with which this Council is concerned.

The Council under its new name replaces, after 11 years of valuable work, the National Council for Combating Venereal Diseases, and points at the same time to an important extension of its work, which will take place without the slightest relaxation of the past work of the Council under its old name in respect of public enlightenment on the problems of and advocacy of the provision by public authorities of adequate facilities for the free treatment of venereal disease for those who need it.

During these eleven years it has been a main part of the work of the National Council to promote the policy and the work of the Ministry of Health and of Public Health Authorities in securing diagnosis and treatment for all, as a means for diminishing infection and avoiding the terrible consequences associated with these diseases; and the Council have reason for the confident view that a wide distribution of information concerning these diseases, which they have been able to furnish, has been an important factor in the medical success which has been achieved.

The extent of the success of the combined efforts that have been made is indicated in part by the fact that during the last four years the number of new patients with syphilis in this country presenting themselves at the treatment centres has declined by nearly 50 per cent.

Great progress has been made since the formation of the purely voluntary organisation of the National Council for Combating Venereal Diseases in 1914. To-day the organisation of the British Social Hygiene Council spreads to all corners of the Empire. It is recognised by and co-operates with Government Departments—the Ministry of Health, the Colonial Office, the Admiralty and the Air Ministry—in providing material for popular enlightenment and in co-operating in all measures calculated to reduce the ravages of venereal disease, receiving grants for certain specified activities. At home active co-operation exists between almost all the Local Authorities in the country and the Council; and out of the 154 areas the Council has recognised Branches in 85, creating centres for the formation of public opinion and for building up protective and preventive machinery in the interests of youth. Sister Councils have been established in Canada, South Africa, Australia, and in six of the Crown Colonies, and a close liaison exists between the Council and Colonial Health Departments throughout the Empire. Although social conditions may vary widely among the different races the medical principles underlying the elimination of venereal diseases remain the same, and the methods which have been adopted at home are proving such an outstanding success that their adaptation to other parts of the Empire is to be warmly advocated.

The British Social Hygiene Council is now extending its attack on venereal disease on social as well as medical lines and is working for the reduction of promiscuity. To ensure the success of this policy increased prominence is being given to "the elimination of those conditions of life which tend to foster promiscuous intercourse and the spread of disease"—the third recommendation in the Report of the Committee of Inquiry on Venereal Diseases.

In this connection attention may be drawn to the fact that the National Council for Combating Venereal Diseases and the Society for the Prevention of Venereal Disease have accepted the Report of the Trevelthick Committee: and as there is now one President (Sir Auckland Geddes) of both these organisations, who is also chairman of the permanently established Liaison Committee between them, the possibility of controversy between them has, it is hoped, been eliminated.

With the direct object of preventing the risk of infection the British Social Hygiene Council is extending its work to include the fostering of character-training of the young. It advocates basing habit formation on a knowledge of the facts of life and on the attainment of right conduct through consciousness of social and racial responsibility. The Council is also working for the eradication of all known forms of commercialised vice and the promotion of adequate facilities for recreation and diversion.

In the Council's teaching the fundamental importance of maintaining the integrity of family life will be an essential object of the British Social Hygiene Council.

During the last eleven years the public has supported the National Council for Combating Venereal Diseases, though its work in the main has been so specialised that apathy might have been excused. On the basis of the success already obtained a fresh appeal is now being made which must commend itself to all those who have the well-being of the family and of the nation at heart, whether as regards the elimination of Venereal Diseases or from the standpoint of a general improvement in the conditions of national life.

On both these grounds we appeal to the general public for support in achieving our objectives.—Yours, etc.,

ACUTE PURULENT OPHTHALMIA.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—During the last fortnight I have seen at least a dozen cases of ophthalmia which proved rapidly fatal to the sight.

Cause.—Impossible to guess without a microscopic examination, which, unfortunately, I could not get done. In one family two children and their mother had the disease. In another the mother and the daughter were the sufferers. In other cases no trace of the spread of infection could be found. Mostly children have been affected; one child lost both eyes on account of panophthalmia. Another woman had such a large central ulcer of the cornea that while she was washing the eye the lens came out by itself, followed of course by panophthalmia. Both eyes were affected in a baby boy, resulting in a large prolapse of the iris in one eye and corneal opacity in the other. The same condition was seen in another girl of about 7 years of age. The infection does not seem to be gonorrhoeal because there was no history of gonorrhoea in any of the families. It was not diphtheritic, because there were no signs of diphtheria in any of the cases. The same may be said about pneumococcal and tubercular infections. It does not seem to be contagious as none of the patients living in the same ward were infected.

Symptoms.—The eye becomes red and swollen, the swelling increases very rapidly and within a few hours it is very difficult to open the eye on account of the swelling. There is an abundant discharge of thick pus; the discharge from under the lids is more serous and the fluid of a yellowish colour. The cornea becomes ulcerated very soon resulting in prolapse or panophthalmia; the pain is very severe and intense. One eye is attacked first but the infection extends to the other eye very shortly.

Course.—The inflammation takes a long time to subside. The discharge is the last thing to decrease. Hot fomentations; blisters, use of caustics, atropine, etc.,

relieve the pain but little and do not save the cornea from sloughing and ulceration.

Treatment.—Silver 2 per cent. was used for a pretty long time to check the discharge and yet it was not quite satisfactory. Mercury cyanide 1 in 50 had no effect in prevention or in lessening the intensity of the inflammation, pain and discharge. The use of atropine and iodoform helped the patients in relieving the pain due to the corneal ulceration and that was all.

N.B.—All these cases were sporadic and belonged to different villages, except in the case of two families in which two children and their mother and a mother and daughter were the sufferers. In all instances the children were the first to suffer. It is rather an uncommon occurrence to see so many cases of the same nature and suffering with the same result in so few days. I have never seen such cases before and I wonder if such cases have been seen and attended to by others. I shall feel grateful if other practitioners would write on the subject giving the treatment they found most useful.—Yours, etc.,

E. CHARLES.

EYE HOSPITAL,

PERACRINA VERSUS MALARIA.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—An article in the May number of the *Indian Medical Gazette* deals with the publication in the *Archiv für Schiffs-und Tropen-Hygiene* on "Peracrina," a new remedy against malaria. The author does not seem to be convinced of the good results of the treatment with Peracrina as recorded in the publication and he believes that some of the curves reproduced might well be employed to shew the natural course of untreated malaria.

It may be that in the short publication referring to the work against malaria of the Swiss Red-Cross Expedition in the famine districts of South Russia, the incidental circumstances connected with the various cases have not been so fully described as to permit a conclusive evaluation of the actual results to readers who had no opportunity of studying the prevailing conditions.

Whoever saw the dreadful general circumstances of the Russian famine would hardly have found any support for the idea that in the cases in question cures could have been obtained without any treatment. It must, on the contrary, be regarded as a fact that a practically complete cure, i.e., a condition of the patient where he was free from fever and complaints and absolutely fit for work, has been obtained through Peracrina in a very high percentage of cases even when other remedies failed. It then often appeared—contrary to what is observed with other methods of treatment—that the state of health and clinical symptoms of the patient (absence of fever, normal spleen, etc.) were those of a normal physical condition while there were still some plasmodia in the blood. In the case of other treatments the plasmodia disappear first from the peripheral blood but often continue to develop in spleen and liver and cause the persons affected to appear still suffering and unfit for work.

The treatment of malaria with Peracrina in Russia was, by the way, only a first attempt carried out under extraordinarily difficult conditions. A second Swiss expedition was despatched in 1924 to the Greek malaria districts, and the results obtained there will be published shortly. They will prove that Peracrina must in fact be recognised as a successful remedy against malaria.—Yours, etc.,

J. WALKER.

BERN,
13th August 1925.

(Note.—There is a paper on the use of Peracrina 303 in malaria in this number of the *Gazette*.—EDITOR, I. M. G.)

A CASE OF FOOD SENSITIVENESS.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR.—In the issue of your *Gazette* for May 1923. Dr. Birendra Mohan Chowdhury reported a case of food sensitiveness, asking for suggestions as to its true etiology and treatment. I venture to put forth my views of the case in the following few paragraphs:—

I consider the case to be one of *urticaria*. The picture delineated by Dr. Chowdhury is of course striking in its manifestations. The symptom-complex is no doubt caused by an acute and transient inflammation, in which mucous membranes of the stomach, eyes, and upper respiratory passages are attacked in conjunction with the skin. The skin lesion described is exactly urticarial,—raised, firm, white, "just like the swelling produced by the bite of red ants." The symptoms of chill, itching, nausea, cough, and running from the nose and eyes, may all occur in an acute attack of urticaria, for urticaria may affect mucous membranes, particularly gastric and bronchial, sometimes leading even to asthmatic symptoms.

As regards the order of appearance of the eruption, the first two sites noted are both within easy reach of the fingers of the right hand, and the wheals are easily evoked by scratching. In reply to the point that the boy's father had similar symptoms in his childhood, it may be argued that without launching into the mystery of a weird symptom-group inherited from father to son, we may plainly say that urticaria is such a common ailment, it is no wonder that the father suffered from it in his childhood. The child evidently gets well with the completion of stomachic digestion, and during this period, what with fullness of the stomach, what with a generalised peripheral dilatation of capillaries and consequent decrease of blood supply to the brain, or what with the particular nature of the toxin elaborated, he easily falls asleep.

The real difficulty is in the detection of the offending agency. Whatever we may call it, idiosyncrasy, anaphylaxis, or supersensitiveness, the poison which produces it cannot be so easily dismissed from the dietary. The attacks have always occurred at the end of meals. In the detection of the offending article, great patience and the cultivation of the detective faculty is wanted. The cause may be discovered by keeping records of the diets on the dates of the attacks and comparing notes. There are indeed many common articles of diet which may produce the eruption in particular individuals. It is difficult to persuade even medical men that such common articles of diet as eggs, milk, and even rice, can possibly act in this way. Careful study, however, will often convince unbelievers. The state of the gastric and intestinal functions should be investigated and set right to prevent the possibility of auto-intoxication, the presence of worms should be thought of, and enquiry into the functions of other important organs should be made to detect any defect.

Treatment should be:—Keeping the bowels open, intestinal antiseptics, removal of intestinal parasites, administration of gastric sedatives, and careful dieting. The following medicines have been found to be useful:—ichthyol in capsules or glycerin, calcium, and magnesia.—Yours, etc.,

R. K. BHATTACHARYYA M.B.

NABADWIP, NADIA.
The 17th July 1925.

"DIAGNOSIS" IN HOSPITALS.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—I find that I omitted a sentence in the original typescript of the paper "Diagnosis in Hospitals" forwarded to you which you very kindly published and so with the object of bringing the omission to the notice of those interested in this paper I shall be much obliged if you will kindly insert this letter in the columns of your valuable *Gazette*.

Nov., 1925.]

After the words "New, disease having supervened" at the end of the top paragraph in the left column on page 413 of the *Indian Medical Gazette* of September 1925 please read "and grant her a register number in the 'transfer' group and thus prevent her disease (c) or (d) from being enumerated twice."

Thanking you in anticipation.—Yours, etc.,

C. C. MURISON, I.M.S.,
Civil Surgeon, Belgaum.

BELGAUM,
30th September 1925.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Lieutenant-Colonel H. Hallilay, M.B., I.M.S., is appointed temporarily to officiate as Civil Surgeon, Simla West, up to the 31st December 1925, *vice* Lieutenant-Colonel Jeudwine, granted leave.

The services of Lieutenant-Colonel R. McCarrison, C.I.E., I.M.S., an Agency Surgeon, on return from leave, are placed temporarily at the disposal of the Government of India in the Department of Education, Health, and Lands, with effect from the 2nd August 1925.

Lieutenant-Colonel R. McCarrison, C.I.E., M.B., I.M.S., is appointed temporarily to the Medical Research Department, with effect from the 2nd August 1925.

The services of the following officers are placed temporarily at the disposal of the Government of Bengal, with effect from the dates on which they assumed charge of their duties.

Captain B. H. Singh, M.C., I.M.S.

" P. C. Banerjee, I.M.S.

" H. E. Murray, M.B., I.M.S.

The services of Captain S. C. Contractor, I.M.S., are placed temporarily at the disposal of the Government of Madras for employment in the Madras Jail Department with effect from the date on which he assumes charge of his duties.

LEAVE.

Lieutenant-Colonel W. W. Jeudwine, C.M.E., M.D., I.M.S., Civil Surgeon, Simla West, is granted leave on average pay for eight months combined with leave on half average pay for four months, with effect from the 1st September 1925.

PROMOTIONS.

Lieutenant-Colonels to be Colonels.

Alexander Fenton, M.B., I.M.S., *vice* Colonel Peter Dee, M.B., I.M.S., with effect from the 9th June 1925. Colonel Fenton's tenure will reckon from this date.

K. V. Kukday, with effect from 28th March 1925, *vice* Colonel J. A. Black, M.B., deceased. Colonel Kukday's tenure of appointment will reckon from the 1st July 1925.

Majors to be Lieutenant-Colonels.

B. E. M. Newland, L. A. H. Lack, N. S. Sodhi, M.C., and W. C. Gray, M.B. —Dated the 1st September 1925.

Captain N. M. Mehta, I.M.S., to be Acting Major whilst holding an appointment with the Egyptian Expeditionary Force, from 22nd November 1918 to 23rd December 1919.

RETIREMENTS.

The King has approved the retirement from the service of Lieutenant-Colonel J. M. Woolley, I.M.S., with effect from the 26th July 1925.

The King has approved the retirement of the following Indian Medical Service officers with effect from the dates specified:—

1. Lieutenant-Colonel L. Hirsch, C.I.E., F.R.C.S.E., on account of ill-health, 26th November 1924.

2. Lieutenant-Colonel J. C. G. Kunhardt, 1st June 1925.

3. Lieutenant-Colonel H. A. F. Knapton, 29th July 1925.

RESIGNATIONS.

The undermentioned officers are permitted, subject to His Majesty's approval, to resign their temporary commissions with effect from the dates specified:—

Captain Bankim Behari Das. Dated the 8th August 1925.

Captain Ram Chand Mahajan. Dated the 10th August 1925.

THE UNVEILING CEREMONY OF THE PORTRAIT OF SIR TEMULJI B. NARIMAN, KT. M.R.C.P., L.M., AT THE GRANT MEDICAL COLLEGE, BOMBAY.

ON Monday, the 16th March, 1925, His Excellency Sir Leslie Wilson, P.C., G.C.I.E., C.M.G., D.S.O., Governor of Bombay, visited the Grant Medical College, Bombay, at 8-30 a.m. to unveil the portrait of Sir Temulji B. Nariman, Kt., M.R.C.P., L.M. He spent over an hour at the College amidst prominent members of the medical profession and students.

The following is a resumé of Captain Bhatia's address, as Dean of the College:—

Your Excellency, ladies and gentlemen,

On behalf of the members of the Grant Medical College, including all the teaching staff and the students, I have the honour to offer Your Excellency a very hearty welcome in our midst here this morning.

Your Excellency has expressed the keenest interest in medical education and in medical relief in this Presidency. In fact, the medical profession in Western India is very fortunate in having at the head of the administration at this moment one who is anxious to do all that is possible to advance its interests. Your Excellency's interest in medical matters is already bearing fruit. We in this College already look upon Your Excellency as a friend, and we therefore doubly welcome Your Excellency on that account.

I shall now briefly narrate the activities of the College during the last year.

Students.—At the beginning of the year the highest number of students on the rolls was 946. Of these 151 left the College on completion of their four years' course of study and 27 junior students also left the College owing to their failure in the University Pre-Final Examination. 121 new students were admitted into the College during the year. The total number at present on the rolls, therefore, is 768 as compared with 946 in 1923-24, 1,142 in 1922-23, 1,161 in 1921-22, 1,155 in 1920-21 and 1,000 in 1919-20. It is anticipated that the number will gradually diminish. *University Examination.*—(i) *Intermediate Examination for the degree of M.B., B.S.* 250 candidates passed; 20 were placed in the first class. Of the successful candidates 23 were lady students.

(ii) *Final Examination for the degree of M.B., B.S.* In Part I, 212 candidates passed. Of the successful candidates 11 were lady students. In Part II, 202 passed. Of the successful candidates 9 were lady students.

(iii) *Examination for the degree of M.D.* Branch I.—(Medicine). Two candidates passed, one with distinction.

Branch II.—(Midwifery). One candidate passed.

(iv) *Examination for the degree of M.S.* One candidate passed.

(v) *Examination for the degree of B.Hy.*

Part I.—Six candidates passed.

Part II.—Five candidates passed.

Countess of Dufferin's Fund Scholarship.—The number of lady students receiving the scholarships of Rs. 20 p.m. each from this Fund is 2.

Other Government Scholarships.—5 scholarships of Rs. 40 p.m. each to students of backward communities. 2 scholarships of Rs. 40 p.m. each to Mahomedan communities.

13 scholarships of Rs. 40 p.m. each to lady students. *University Training Corps (I. T. F.).*—There are two platoons in this College. In each platoon there are

1 commissioned officer, 5 non-commissioned officers, and 33 privates.

General Remarks.—Your Excellency, the history of the College since its inauguration is one of steady and consistent progress, but during the last two or three years certain important changes have taken place which promise to increase the efficiency and usefulness of this institution to a still greater extent. These changes are as follows:—

(1) The introduction of a new curriculum for the M.B., B.S. degrees in order to meet the requirements of the British Medical Council. The two important effects of this change are:—

(a) That the students now do three years' hospital work instead of two.

(b) That the standard of preliminary education required for admission to the College is raised from the previous to the Intermediate Science Examination. In both respects the change is very wholesome.

(2) Side by side with the change in curriculum, the number of admissions in the College has been restricted to 120 per year. The admissions now take place only once a year instead of twice as was the case before.

(3) The third important development consists in the increased facilities for clinical instruction offered by the conversion of the Gokuldas Tejpal Hospital into a teaching institution. Our students attend the medical and surgical wards of the hospital, and this is a great help in view of the large number of students who seek instruction in this College.

(4) There has been an increase in the facilities for practical instruction in midwifery and gynaecology also.

(5) In the teaching staff, the most vivid change is the great increase in the number of men who work in an honorary capacity. At present we have the following number on the honorary staff of the College and Hospital:—

Medical.

Out-patient physicians	3
In-patient physicians	2
Associate Professor of Medicine	1

Surgical.

Out-patient surgeons	3
In-patient surgeons	2
Associate Professor of Surgery	1

Midwifery and Gynaecology.

Associate Professor of Midwifery and Gynaecology	1
--	----	----	---

Your Excellency, the chief reproach of this College has been that it was too crowded, that we had more students than could be properly trained. That reproach was to a great extent justified. But now, with a reduction in the number of admissions, raising of the standard of preliminary education, increase in the number of years to be devoted to clinical instruction, increased facilities for medical, surgical and maternity work, and a larger number of well qualified teachers, I am extremely optimistic about the future and am confident that the reproach will soon completely disappear. In the Intermediate classes we are already beginning to feel the beneficial effect of these measures. The classes are smaller, the tuition is improved, and we are able to get through more work than before. This College by virtue of its history and noble traditions, also by the high standard of teaching attained, has rightly been regarded as the premier medical college in India. Its Physiological Laboratory is the best equipped in India; in fact some of the distinguished foreign visitors give testimony to the fact that it is second to none in the world. Its Anatomy Department is again one of the best in this country. In the Anatomy School a department of embryology is springing up, which is still in an early embryonic state, but gives promise of developing into a vigorous manhood before long.

I would be failing in my duty if I did not state briefly our most urgent needs in the immediate future which make for increased efficiency and usefulness. These are:—

(a) Suitable hostel accommodation for the students, the present hostel having been recognised by all to be unworthy of this great College.

(b) The need for a new and better equipped bacteriological laboratory.

(c) Increased number of beds in the Jamsetjee Jeejeebhoy Hospital, which are urgently needed for purposes of clinical instruction apart from the question of medical relief.

(d) A clinical laboratory in the hospital under the direction of a clinical pathologist.

(e) A nucleus of a centre for teaching dentistry and a dental hospital.

All these requirements are urgent. They are already under the consideration of the Government, and I have no doubt that they shall have Your Excellency's full sympathy and come to fruition in due course.

I now request Your Excellency to unveil the portrait of Sir Temulji B. Nariman. It is a humble token of the regard we, in the Grant Medical College, have for him. His associations with the College have been lifelong. We shall consider it a matter of great pride to have his portrait in the College gallery, where we have collected the portraits of some of those able and devoted men who have left their mark in the history of the College and have helped to make it what it is.

Abstract from the "Times of India," dated 17th March, 1925.

His Excellency, who made a short speech, said:—

"I thank you all most sincerely for the way in which you have received me on my first visit to your College. It is always a great pleasure to me to meet college students of the Bombay Presidency, for, in making their personal acquaintance, as I try to do on every possible occasion, I get to learn the views of the younger generation on many important topics. I was very glad to hear, in the address which has just been read, the appreciation expressed of the work performed by Major Higham, the last Dean of the College. From all that I have heard about the affairs of the Medical College since I came to Bombay, I have gathered that all you have said about Major Higham's work is thoroughly well deserved, and that his services to the College during his term of office were most valuable.

There has been, as your annual report shows, a small reduction in the number of students attending the various classes. Before I left England, I had an interview with the principal medical authorities there, who informed me that they viewed with considerable anxiety the inadequacy of the training of medical students in Bombay, particularly as regards practical work in midwifery. It is a fact that, about then Government were faced with the position that it was impossible to provide adequate training, especially in midwifery, for the very large number of students who sought to obtain it. On account of the financial position, and for other reasons, it was not possible immediately to extend the facilities for practical instruction in that direction, and the only alternative was to reduce the number of students by raising the standard of admission to the College. The policy which we have adopted has, I am glad to understand, met with the approval of the medical authorities.

Hospital Facilities.

I will not deal at length with the hospital reform scheme, details of which have been published in the press, and which has been accepted by the Municipal Corporation of Bombay and by the Legislative Council, for a wide extension of hospital facilities in Bombay, and I hope that when that scheme goes through there will be ample provision for all kinds of practical medical instruction in connection with the hospitals. I realised the urgent necessity for action to be taken in this matter as soon as I arrived in Bombay, and, while there has been delay, that delay has been unavoidable. I am glad to think, now, that it will be possible in a short time to go ahead, and already several useful propositions have been put before me—propositions not only useful, but which include some very generous proposals; and I

Nov., 1925.]

have every confidence that we shall be able, during the next year or so, to lay the foundation stone of a scheme which will provide hospital accommodation and facilities for medical training worthy of this great city. I should like to say for myself, as well as on behalf of Government, how very grateful we are to the Municipal Corporation for all the help they have given us by enabling the students to receive instruction in midwifery in the municipal maternity homes. The assistance which they have given us at a difficult time has proved to be of the greatest value, and I am sure that all who have the welfare of the medical profession at heart will appreciate the generous manner in which the Corporation has co-operated with Government in this very important direction.

The Money Question.

Like most institutions in this Presidency, you have one or two wants which I should be glad to see immediately satisfied. At the same time that is a question of money, and I am afraid that Government, has not, at present, at its disposal sufficient funds to enable it to undertake any new construction on a large scale during the coming year. I am fully in agreement with all the proposals which Captain Bhatia has mentioned to improve the efficiency and usefulness of the College. I have been told before of the urgent necessity for more suitable hostel accommodation, of the need of both a bacteriological and clinical laboratory, and I find it really difficult to understand how, in this city, there has not been established, long before now, a centre for teaching dentistry—a branch of medical science which is recognised everywhere, in these days, as one of the most important. It is, of course, quite impossible for me to say when these very necessary needs will be met, but I can assure you that I shall do everything that lies in my power to assist them, as I realise they are important, not only to you students but to the whole future of the medical history of the Presidency.

It has been, as I have said, a great pleasure to me to come here to-day and to meet you. Although I have not been here before, I have heard a good deal about you, and I know well that you, like other medical students in every other part of the world, have a reputation for keenness and thoroughness in every form of sport, combined with those high spirits for which practically every medical student is noted. It was only yesterday that I was reading an account, and looking at pictures, of one of your students, Mr. Nanjiani, who apparently possesses powers of strength and endurance of a most extraordinary character, and I hope that some day I shall have an opportunity of seeing some of his feats—although I can assure you that I have no desire to meet him personally except in an entirely friendly capacity.

Before I perform the duty of unveiling the portrait, I should just like to add that I wish every student here all success in life. I trust that each one will be as fortunate as he himself hopes to be in his examinations, and, when he goes out from this College as a member of the most noble profession there is in the world, he will rise to a high position in that profession, and prove himself worthy of the College which started him on his professional career.

A Distinguished Career.

I come now to what is, for me, a very pleasant duty, namely, the unveiling of the portrait of Sir Temulji Nariman. This College and Sir Temulji may be described as practically contemporaries, but the College has slightly the better of Sir Temulji, as it was started in 1845, and he did not see the light of day until three years later, at Navasari. I do not know whether he took much interest in this College for the first few years of his life, but I learn that he joined this College in his nineteenth year, that he passed out five years later, and that from the day he entered it till now he has never ceased to support the Grant Medical College with his advice and assistance and to a very considerable

extent with money also. From the early days of his professional career he interested himself in midwifery and in 1884 he founded the Parsi Lying-in Hospital, which was the only hospital of its kind in India at the time, and which will remain a lasting monument to Sir Temulji's zeal and devotion to the cause of maternity work which he has always had at heart during his long and distinguished professional career.

From one of the many donations which he has placed at the disposal of this College, I infer that Sir Temulji and I are in complete agreement in regard to the necessity of College students engaging in play as well as in work, for I find that, as a Trustee of N. J. Wadia Charities, he gave Rs. 20,000 for a pavilion for the Grant Medical College Gymkhana at Kennedy Sea face, and indeed, this pavilion owes its existence very largely to Sir Temulji's exertions. I am very glad to find that one who is looked up to as a leader of medical education in Bombay should have adopted in this very practical manner, the policy which I am always prepared to advocate in connection with the colleges of the Bombay Presidency.

Sir Temulji has held many public and professional positions in which he has exhibited great ability and tact. He has been associated for many years with the Bombay Medical Council, the College of Physicians and Surgeons, the Bombay Presidency Nursing Association, the Bombay Municipal Corporation, the Bombay Legislative Council, and with numerous charitable, educational and religious institutions. He has played a leading part in the organisation and development of medical education and of the medical profession during the last 50 years, and in 1914 he received a fitting reward in the Knighthood conferred upon him in that year by His Majesty the King.

We are very glad to see Sir Temulji here with us to-day looking still as hale and hearty as ever. Personally, I have been glad to count Sir Temulji as one of my friends on whose fairness and right judgment I could safely rely. He is one of the greatest sons of the Grant Medical College in Bombay; all those connected with the College must be proud of him, and you will all join with me in hoping that he may still enjoy many years of happiness and usefulness to this College and city. I have much pleasure now in unveiling the portrait of Sir Temulji Nariman."

Sir Temulji in reply considered himself rightly honoured on the unique occasion when his portrait was unveiled not only in his life-time but in his presence. Sir Temulji then re-capitulated several pleasant and memorable incidents and remarked that he had passed his run of jubilees. His own jubilee was celebrated 27 years ago, and his wedding jubilee long since. Two years ago the College celebrated his jubilee in connection with the medical profession. He considered this a great event in his life and sincerely thanked His Excellency for his good wishes.

Colonel Novis proposed a hearty vote of thanks which was seconded by Dr. Dalal.

NOTICES.

"HEALTH ORGANISATION IN JAPAN."

THE Health Organisation of the League of Nations has just issued a volume entitled "Health Organisation in Japan."

The volume contains thirty-six conferences given in Japan on the occasion of the interchange study tour organisation for medical officers of health from the Far Eastern countries by the Health Organisation of the League of Nations (October to December 1925).

This publication exists in the English language only and has been printed in a very limited quantity. A copy may be ordered through any of the League agents in the various countries or direct from the Sales Department of the League of Nations, Geneva, Switzerland. The price is 5/-; \$1.25 or 6 Swiss francs.

"A SCHEME FOR THE IMPROVEMENT OF
THE HEALTH OF VILLAGERS, AND RURAL
SANITATION."

PARTICULARS AND CONDITIONS OF AWARD
OF A GOLD MEDAL.

A GOLD MEDAL called the "Rai Sahib Shambhu Dayal Sahib Gold Medal" will be presented for the best prize essay on a public health subject to be announced each year.

2. The subject for the essay for 1925, is "A scheme for the improvement of the health of villagers, and rural sanitation."

3. The competition will be open to the general public of United Provinces.

4. The essay must be written in Hindi and should not exceed 3,000 words in length.

5. Essay should reach the Director of Public Health, U. P., Lucknow, by the 31st December.

6. The name and address of the competitors must be distinctly written on each essay submitted and the envelope should have the words "Prize Essay" in the top left hand corner.

7. The Director of Public Health, U. P., shall judge the merit of the essay and his decision with regard to the award of the Medal shall be final.

No correspondence will be entered into on the subject of the competition.

No essay will be returned.

BRAND & CO'S INVALID PRODUCTS.

MESSRS. BRAND & Co., LTD., London, have been invalid food specialists for nearly ninety years and during the whole of that time have held the appointment to supply their products to the Royal Household.

Brand's Essence of Chicken is a marvellous stomachic without an equal in cases of gastric trouble, fevers, impaired digestion, nervous prostration and similar diseases and is prescribed by the leading medical men throughout the world.

Their Indian representative, Mr. A. H. P. Jennings,

Block E., Clive Buildings, Calcutta, will at all times be pleased to supply literature and price lists upon request.

"TABLOID" HEXAMINE AND METHYLENE
BLUE.

"TABLOID" Hexamine and Methylene Blue is a combination of three grains of hexamine with a quarter grain of methylene blue. The therapeutic activity of hexamine is enhanced by the addition of methylene blue which possesses analgesic as well as antiseptic properties and is equally active in acid or alkaline urine. The combined product should be of value in a variety of biliary and genito-urinary conditions, before and after operations on the kidneys and prostate, in pyelitis, urethritis and septic urinary conditions. "Tabloid" Hexamine and Methylene Blue is sugar-coated and the ingredients are of the high standard of purity and reliability associated with "Tabloid" products.

PHOTOGRAPHIC SIGNPOSTS.

For many years Burroughs, Wellcome & Co. have made it an annual practice to issue a most attractive and really useful booklet on photography.

The booklet "Photographic Signposts" will be sent post free to all readers mentioning this paper and applying to Burroughs, Wellcome & Co., Post Box 290, Bombay.

DIFCO PRODUCTS.

We have just received a very useful little booklet on "Endocrines, Enzymes and Protein Compounds" published by Digestive Ferments Co., Detroit, Michigan, U.S.A., proprietors of the Difco products.

As a result of research extending over a period of years, and a study of the medical and scientific literature available, they have prepared from time to time bulletins giving chemical and therapeutic information in connection with the manufacture and use of "Difco" digestive enzymes and animal derivatives.

This material has been compiled and amplified. It is now presented in the form of a booklet which they believe will prove a convenient reference manual for the manufacturing pharmacist and chemist. The booklet, comprises a summary of the available authoritative information on the subject of endocrines, digestive enzymes and protein compounds.

The Scientific Supplies (Bengal) Co., 29-32, College Street Market, Calcutta, are sole agents in India, Burma and Ceylon for all preparations of the Digestive Ferments Co. and they hold a large stock of their goods.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to the *Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of the *Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

A PLEA FOR RESEARCH IN THE TREATMENT OF SQUINT.

By HENRY SMITH, C.I.E.,
LIEUTENANT-COLONEL, I.M.S. (Retd.),

THE present position of the treatment of squint leaves much to be desired. I use the term squint to cover non-paralytic cases and cases in which spectacles are not sufficient. The necessary operative treatment is essentially cosmetic and cannot aspire at aligning the axes in physiological position.

Is it not possible to shorten the rectus muscle at fault without any cutting operation? I hold that it is possible. Take the case of any limb muscle relaxed for, say, 14 days as in the case of fractures in which the joint is fixed in a flexed position. At the end of that time the muscle is shortened and will remain shortened if not forcibly stretched by the surgeon. Take the case which we have often seen in which after flail union following fracture, say of the humerus or of the leg bone, in which we have excised three inches of the bone or bones and brought the ends together. In these cases the muscles are three inches too long when we have finished the operation. The muscles in these cases always contract up to the length necessary to operate the limb. They contract very much more quickly if submitted to electrical stimulation twice daily for a few days. A non-paralysed muscle always contracts up to hardly what we may call a normal tension tonus. In the above cases in doing so it has permanently shortened. Can we not by utilising the principle involved shorten a rectus muscle of the eye? I am confident we can do so. When in Canada four years ago, a girl of ten years of age was brought to me in a small town where I was having a holiday; she had 30 degrees of external squint. I submitted the rectus at fault, under the influence of cocaine for the conjunctiva, to a weak faradic current for 5 minutes at a time, morning and evening, for 5 days. At the end of this time she had but 2 degrees of squint. I had to leave and ordered her the addition of a pair of 1 D. prisms to her glasses. She was intelligent; the observations were taken with a light as the object, without coloured glass or Maddox rods. She could tell exactly where the second light was and from this and the distance I could do the calculations. I have heard from her not long since and she has steadily seen single since the time of treatment.

If I could have used a fairly strong current results would have been more rapid. When I used a strong current the child got nausea and even when I used it for a second sitting nausea soon set in.

There is no risk. If we succeed we can put the axes in physiological position; no other procedure up till the present can aspire to do this.

THE TREATMENT OF INCISIONAL SINUSES.

By H. HALILAY.
LIEUTENANT-COLONEL, I.M.S.,
Civil Surgeon, Simla.

It sometimes happens in the course of an abdominal operation that the wound in the parietes becomes infected, possibly owing to defective technique, or to a breakdown in the sterilising arrangements, or to some chance contamination of the suture material.

Be the cause what it may, the patient is left with a persistent sinus or sinuses which discharge intermittently or constantly, a state of affairs which is a cause of great annoyance and distress to the patient, and very often of loss of prestige to the surgeon.

Abdominal wounds seem peculiarly prone to the development of sinuses, possibly owing to the fact that it is difficult to apply effective pressure in this situation, there is a greater liability to post-operative oozing and the consequent formation of dead spaces in which organisms can multiply.

As a rule, the wound is undermined for the whole of its original length. There may be one or more openings in the scar through which the discharge escapes, but usually the fat and subcutaneous tissues will be found to have united over the sinus which is situated between the sheath of the deep muscles and the subcutaneous tissues.

We thus have a sort of tunnel of granulation tissue placed on the deep fascia and surrounded by a sheath of scar tissue, which becomes denser the longer the condition lasts.

The denser the envelope of scar tissue becomes, the more difficult it is for the local and general defensive mechanism of the body to destroy the invading organisms which infect the lining granulation tissues of the sinus, which constitutes what the older pathologists would describe as a true pyogenic membrane.

It is no doubt due to this impenetrable wall of scar tissue that the chronicity of the sinuses is due; they may persist long after the infected suture material has been absorbed.

In one case which had been operated on for appendicitis in 1918 the wound had supplicated and a sinus had persisted until 1923 when I excised the whole track of the granulation tissue. Although there was no trace of the original suture material in her case, there was none the less a very extensive sinus which had undermined the subcutaneous tissues considerably, and which displayed no signs whatever of healing.

One of the most striking features of these persistent sinuses is the evil effect which they

exercise on the mind of the sufferer, out of all proportion to the area of tissue involved.

The sickness of hope deferred, constant disappointment, endless tinkering with the wound, the presence of an unclean discharge, often in a woman who may have a most exquisite standard of personal cleanliness, all combine to produce a condition of depression and even hysteria in the patient.

The surgeon who has seen a few of these sinuses will realise more keenly than ever that no care, however meticulous, can be too great to avoid infection of the wounds which he inflicts.

That a patient who has been sent into a nursing home to undergo an operation which he or she was told would incapacitate him or her for two or three weeks at the most, should be let in for months or years of this kind of suffering and disability is a blot on the fair fame of aseptic surgery. It may be said that some of these regrettable incidents are unavoidable; this may be so, but it is the duty of the surgeon to see that they are reduced to the irreducible minimum.

TECHNIQUE.

The skin having been carefully cleansed by whatever method of disinfection is favoured by the surgeon, the sinus is opened along its entire extent so that the tunnel is converted into a gutter. The first knife and all instruments used in opening up the sinus are now discarded, and an entirely fresh set of instruments employed. The ribbon of granulation tissue is now dissected out, every endeavour being made to remove it in one piece. With it is also removed the surrounding wall of dense scar tissue. All that now remains to do is to take away a thin slice of the apposing surfaces of the wound down to the oozing gutter left by the removal of the ribbon of granulation tissue. Here again it is necessary to call for a fresh relay of instruments, as we wish at all costs to avoid any chance of reinfected the freshened wound.

This sounds more formidable than it really is, because the instruments used are few, mostly knife and forceps.

The wound is then carefully swabbed out with tincture of iodine to destroy any chance infection that may have been left behind, and closed by through and through sutures of silkworm gut, in such a manner as to obliterate all dead spaces. No vessels are tied, no suture materials are left in the depth of the wound.

Union as a rule takes place in ten days by first intention, this applies even in cases that have been going on for years, few operations are as gratifying in their results to both surgeon and patient.

SOME ILLUSTRATIVE CASES.

Case 1.—Mrs. G., aged 56. Operation some three months previously, copious discharge, considerable pain and very great mental distress amounting to hysteria.

The sinus was opened up and the track of granulation tissue was dissected out, a suture of phosphor bronze about four inches in length was found tethered to the sheath of the rectus and was removed at the same time. The wound edges were then freshened and the wound closed by through and through sutures of silkworm gut.

Union by first intention was found to have taken place when the sutures were removed in ten days' time.

Case 2.—Mrs. D., aged 32. Operation for appendicitis in August 1917, wound infected and persistent sinus until May 1923, when I excised the sinus.

This patient had suffered much at the hands of many doctors and had lost all hope that the sinus would ever heal. Her morale was much lowered and owing to the fact that exercise had been interdicted, she had put on a great deal of weight. The sinus was dissected out in one piece, the wound freshened, and closed by interrupted silkworm gut sutures. Union by first intention occurred and the stitches were removed on the tenth day.

The moral effect upon the patient was remarkable, she regained her cheerfulness and lost all neurasthenic symptoms as soon as the wound healed.

Case 3.—Mrs. E., aged 38. Operation for appendicitis some five months earlier. Infection of the wound, persistent sinus. Patient very depressed mentally and run down physically. Had been in bed since the operation.

Complete excision of the old sinus and scar tissue, sides of the wound freshened, wound closed by through and through sutures of silkworm gut. Union by first intention. Immediate amelioration of all neurasthenic symptoms, and she commenced to put on weight as soon as the wound closed.

These three cases are sufficient to illustrate this brief article; it would serve no useful purpose to multiply them. I have merely quoted them to show how rapidly these troublesome sequelæ can be cut short, and how rapidly the sufferers regain their former morale and health as soon as the sinuses close.

PELVIC MEASUREMENTS IN INDIAN WOMEN.

By G. STAPLETON, M.D., B.S. (Lond.),

Women's Medical Service.

Acting Principal, Women's Medical School, Agra.

As medical students in this country usually read English midwifery text-books, and not infrequently forget the difference in stature that exists between women of the East and West, it was thought advisable to take a series of pelvic measurements in Indian women to see how far they varied from the text-book figures. Two hundred cases were examined, all being patients who had been admitted to the Dufferin Hospital at Agra for labour at or near full term. They were consecutive as far as possible, only certain patients who had been transferred to another ward for sepsis and others who left the hospital without permission being omitted. The examination was made at the time of their discharge on the 8th or 10th day after delivery, or later, and the measurements were all made by one observer in order to avoid any variation due to the personal factor.

The women were mainly of the middle and poor classes, and the majority came from Agra

city. Nearly three-quarters were Hindus, three Christians, two Parsees, and the rest Mussalmans. Of the total number, 25 patients were considered to have contracted pelvis of some variety.

EXTERNAL MEASUREMENTS.

The mean external pelvic measurements of the whole 200 patients, worked out to the nearest second decimal figure, were found to be:—

Intercristal	..	9.60 inches.
Interspinous	..	8.54 "
External conjugate	..	7.07 "

The intercristal measurement was taken between the outer lip of the widest part of the iliac crests, and the interspinous between the most prominent part of the anterior superior spines.

If the 25 cases of contracted pelvis were excluded, then the figures were:—

Intercristal	..	9.69 inches.
Interspinous	..	8.67 "
External conjugate	..	7.22 "

Only two of the whole series showed an intercristal measurement which approached the English standard, i.e., 11 inches or over.

THE DIAGONAL-CONJUGATE.

All the patients were submitted to a vaginal examination and an attempt made to measure the diagonal-conjugate with the fingers. It will be seen from the following table that the promontory of the sacrum could be felt in over two-thirds of the cases:—

Promontory not felt in 63 cases.		
D.C.	4½ inches	10 "
"	4½ "	65 "
"	4½ or 4+	39 "
"	4 "	13 "
"	3½ "	4 "
"	3½ "	2 "
"	3½ "	2 "
True conjugate 2 fingers' breadth		1 "
Conjugate not taken		1 "
		200

In the cases of the first group, it could not always be taken for granted that the D.C. was 4½ or more inches, as failure to reach the promontory was sometimes due to factors such as a recently healed tear of the perinæum against which it was unwise to exert much pressure, rigidity of the pelvic floor, loaded rectum, rigidity of the vaginal vault, and in one case, great contraction of the bony outlet.

In the second group, the opposite conditions obtained, and it was only owing to the extremely relaxed state of the perinæum that the fingers could stretch 4½ inches. In the one case in which the conjugate was not taken, there was an extensive scar of the vaginal vault due to recent incision for total atresia of the cervix.

From the above figures one can calculate that the mean of the diagonal-conjugate in Indian women patients in Agra is nearer 4½ than 4¾ inches.

CONTRACTED PELVIS.

All the patients in whom the diagonal-conjugate was found to be 4 inches or less were considered to have contracted pelvis. Three cases of slightly flattened pelvis with a diagonal-conjugate of 4½ inches or just under were also included in this group.

The cases were classified as follows:—

1. Simple flat pelvis	..	5 patients.
2. Generally contracted pelvis	..	8 "
3. Osteomalacia pelvis	..	12 "
(sometimes of the severe triradiate type)		25

In a large proportion of the cases in the first two groups the contracted pelvis was found accidentally, as three of the simple flat and six of the generally contracted type had had normal labours, while the remaining two of the latter class succeeded in delivering themselves after some delay. Two of the cases of flat pelvis required craniotomy as the diagonal-conjugate was only 3½ and 3¾ inches respectively, and the children were dead. In the osteomalacia class, nine underwent Cæsarian section, one was a forceps case, and the remaining two delivered themselves, though in one of these labour was abnormally prolonged.

WEIGHT OF THE INFANTS.

The average weight of the infants whom the mothers thought they had carried to full term, worked out to just under 6 lbs., i.e., 5.96 lbs. Some of these babies however were very small and puny, and probably not quite full term, so that the average weight at the full nine months should have been a little over 6 lbs.

As regards delivery, the size of the child in relation to the mother's pelvis was of far more importance than its actual weight and the actual measurements of the mother.

In some cases however one was surprised by the comparatively large size of the baby that came normally through a small internal-conjugate. One 4-para with a diagonal-conjugate of 4 inches delivered herself of a living 7½ lb. child in 21 hours, and said that all her previous labours had been quite normal, and another 3-para with D.C. of just over 4 inches had a 7 lb. child after 15½ hours in labour, and gave a similar history. The soft heads of Indian babies which appear less extensively ossified than those of European children may be the cause of the large amount of moulding that can take place.

CONCLUSIONS.

1. The average external pelvic measurements of Indian women in the Agra District, excluding those with abnormally small pelvis, are:—

1. S. under 8½, I. C. under 9½, E. C. 7½ inches.
2. The diagonal-conjugate is on the average 4½ inches.
3. The average weight of the babies at birth is 6 lbs.
4. Slight grades of flat pelvis are found apart from any history of osteomalacia or rickets.

FAMILIAL TREATMENT OF THE INSANE.

By OWEN BERKELEY-HILL,

MAJOR, I.M.S.,

RECENTLY I have come to know that a body of representative opinion in this country decided unanimously that familial care of the insane in India is "impossible." As the reasons alleged by these persons in support of their opinion are by no means evident and as each single individual concerned has never had any personal experience of the familial treatment of the mentally afflicted, we are at liberty to presume that the sphere of mental medicine in India has got to share the lot of every other domain of human activity and suffer from prejudice unadulterated by one element of rationality. Is it too late to attempt at this eleventh hour to introduce a leavening particle of fresh thought into the existing conceptions of the care and treatment of the insane? Is it no longer possible to persuade people that we are perhaps lingering over-long at the stage of building huge caravanserais in which the insane have an environment which still leaves much to be desired for this type of system? Are we not perhaps hypnotised by the idea that we have reached the limit of endeavour to alleviate the lives of those who are victims of mental disease? Is this extreme measure of segregation away from society the ideal to be aimed at for the treatment or comfort of our patients? Is it also good for the social community? To a large extent at present so-called treatment merely means institutional confinement. The attitude of the medical profession and even of many psychiatrists is such that they tend to regard relegation to a mental hospital as the safest and most correct procedure when an individual shows any signs of mental abnormality. It is grievous to realise the number of cases which are disposed of in this manner, but which with care and understanding never need have been secluded within walls. For years, I have held that familial treatment of Anglo-Indian and Indian insanes is not only a possible but an inevitable development. I have studied a great deal of literature on the subject and have made a thorough examination on the spot of the greatest experiment in familial treatment of the insane to be found in the whole world, namely the colony at Gheel in Belgium. A very interesting account of the colony at Gheel was published by Dr. C. Stanford Read in the *Journal of Mental Science* in 1921, and as it is impossible in my opinion to improve upon it, I shall quote it extensively.

"Gheel is a small Belgian town not far from Antwerp having a population of over 15,000 in its nine parishes. Within this area some 1,500 certified mental patients are boarded and cared for in households. Under this system the patient lives as one of the family and has no restrictions placed upon his freedom, except that he must

be 'home' by 8 P.M. in the summer and by 4 P.M. in the winter, and is not allowed to be served with alcoholic refreshment without special permission. A patient arriving at Gheel, unless there are special indications otherwise, is placed in the Infirmary for observation, so that the Medical Director can study the type of case he has to deal with and can make sure that it is one suitable for the system. If at any subsequent time any illness should arise requiring special medical attention, or should any episodic outbreak of recalcitrancy or violence be manifested, the patient can be temporarily transferred to this Infirmary where he will be under a stricter and a safer *régime*. As soon as a case is sufficiently understood, the question as to which family he or she shall be relegated to has to be decided. This is always an important point, which depends not only on the social class of the individual but upon the patient's choice and perhaps that of the relations, and also upon the Medical Director's knowledge of the special adaptive requirements needed, and the families where he is most likely to meet such. It not frequently happens that a patient has to change his *milieu* more than once before he feels he is in a correct environment in which he can feel at home. The families themselves take a highly active interest in the happiness and welfare of their charges so that their co-operation in the work may always be counted upon. This care for the mentally afflicted is quite voluntary and any *nourricier* has to be able to show evidence of an irreproachable character before the great responsibility is allowed. Indeed, any family to whom it is not considered advisable to entrust a patient, lives in perpetual shame. The Medical Director told me that no man could get his daughter married if it could be proved that a patient had never been allowed to dwell in the girl's family. The pecuniary emolument is very small. At the time of my visit what is termed 'First Class' accommodation cost six hundred francs a year, that is about Rs. 85. This sum procures a pleasant bed-sitting room and excellent food.

"Through Christian influence and through the accumulated traditions of twelve centuries, the insane have come to be regarded by the people of Gheel, not as individuals who are to be shunned and feared and placed without the pale of society, but as sufferers from disease which may be cured or alleviated, or who, at any rate, may have their lot rendered happier and less burdensome by human understanding, kindness and sympathy. The *nourricier* takes a pleasure and much trouble in smoothing away the adaptive difficulties which beset his patient's path, and only too gladly works hand in hand with the medical officer with this common object in view. It might be supposed that the familial care system involving an intimate mixture of the insane and sane must in time have a deleterious effect on the latter; that with so much liberty given to those who presumably lack inhibition, immorality is bound to be rife; and

that the possible dangers of escape, violence and suicide will be difficult or impossible to control. In practice none of these fears have been found verified. The mental health of the population of Gheel has always compared most favourably with that of other Belgian towns; immorality and illegitimacy are at a minimum; and it is very infrequently that any injury to person or property is reported. The contentment of the great majority of the patients is such that the idea of escape from their environment does not easily enter their minds. Further it seems that all forms of mental alienation can be treated on the familial system, though it is obvious that those who after observation show a continued anti-social tendency, and those who thereby may be a danger to themselves and others, or who would offend the public decency, must be segregated away from the community in institutions. The experience of Gheel demonstrates that many insanes who show dangerous proclivities in their own homes become quiet and peaceful in the colony. It is recorded that a violent maniac who had to be brought to Gheel tightly bound down with ropes to a hand-barrow and guarded by two men, which was thought necessary to ensure safety, permitted himself to be led about contentedly by a child of his *nourricier*."

It may here be asked whether such a system as that of Gheel proves its superiority by showing a greater percentage of recoveries. This can hardly satisfactorily be answered, because in this instance we are only dealing with numbers specially selected, and so any statistics would be extremely misleading. Such a question, however, is to some extent beside the point, for though it might be possible that with our present great ignorance of the pathology of mental disease the ratio of cured might be no higher, the fact remains that under such a system the patients live a more normal life, one easier of adaptation and therefore a happier one, and it too seems proved by experience that truly demented states are thereby lessened, prevented, or retarded; for modern psychopathology teaches that much that passes for dementia is the giving up of all attempt at adaptation because the task is too formidable.

Now, as far as I am aware, the gist of the objections to the introduction into this country of the Gheel system, or some modification of it, is that it is incompatible with the manner of life of the people. Certainly want of pity is more characteristic of Asiatics than of Europeans but this defect is not irremediable. At the present moment in India a good deal is being done in this direction by societies for the welfare of children, the prevention of cruelty to animals, and so on. In any case, I am strongly of the opinion that the supposed impracticability of the adoption of some familial system in this country is much overrated and founded largely upon inertia, ignorance and apathy. It is quite true that the Gheel system is the slow and successive product of centuries and that in a day one could not imitate

it in India. It is, therefore, that the more intelligent portion of the community wants educating to view mental affliction in a very different light from the way in which it is viewed at present. Probably no better education could exist than the establishment of experimental colonies at such places as Ranchi and Bangalore. It is needless to say that opposition would be met with on every hand, even from the medical profession itself; but in course of time arguments against the system would be proved to be baseless, and mental hospitals would only exist for those who by no manner of means could be looked upon as possible members of the social community, even under supervision. For the success of such a colony the Medical Director must be a physician possessing special attributes. His psychiatric knowledge must be extensive and practical; he must be a man of the world and be capable of taking wide viewpoints; he must essentially be humanistic, patient, and sympathetic, and be capable of rapidly gaining the patient's confidence and be looked upon as a friend as well as a physician; he must be a good organiser and possess infinite tact to smooth away the often trivial adaptational difficulties of those under his care.

He must not be, as are most medical directors of mental hospitals, clamped down under the fetters of petty detail and fed upon the mean diet of compromise and routine. He must be protected from interference from the most recent products of political quackery, that is to say, creatures ready at any moment to institute the meanest of intrigues so long as there is a ray of hope that some political advantage, however small, may be gained therefrom. Lastly, he must be paid a reasonable salary and permitted to have the freest hand in the selection of his staff as well as in the rejection of persons who turn out to be either fools or shirkers, or both.

THE ABUSE OF EMETINE.

By G. R. McROBERT, M.D. (Aberd.), M.R.C.P. (Lond.),
D.T.M. & H. (Eng.),

CAPTAIN I.M.S.,

Dera Ismail Khan.

THE addition of emetine by Sir Leonard Rogers to the therapeutic armamentarium of the tropical practitioner has undoubtedly led to great improvement in the treatment of amoebic dysentery and has proved a perfect Godsend in the treatment of amoebic hepatitis and liver abscess.

As is very apt to happen however when new and potent drugs are introduced, emetine has been taken up somewhat too enthusiastically and is looked upon by many practitioners as a sort of panacea for all intestinal troubles and as the chief drug indicated in all cases of intestinal flux and of obscure abdominal pain.

As a result, not only is valuable time wasted in the diagnosis of cases by the application of that abominable, though classic, diagnostic

measure—the therapeutic test—but many patients who present no indications whatever for the exhibition of emetine are subjected to the discomfort and—in some cases—danger of injections of this alkaloid.

The practice of “in diarrhœa try the effect of emetine” is almost as common as that of “in fever try the effect of quinine” and is even more disastrous in its results; and it is on account of a growing conviction of the urgent and very real necessity for a much more widespread recognition of the harm done by the administration of emetine at random, especially to patients who are up and about, that the writer has been tempted to put forward these remarks so soon after the publication in these pages of the very comprehensive and admirable articles on the dysenteries of India by Majors Acton and Knowles, I.M.S.

During the first two years of his service in the East, the writer had the good fortune to work under the daily supervision of a distinguished medical toxicologist who was wont to lay great stress on the fact that emetine is a highly toxic drug which is to be administered only when absolutely indicated and with the patient at rest in bed.

The first and foremost point to be attended to is that emetine should only be given when the intestinal trouble is caused by the *Entamœba histolytica*.

In military practice microscopic diagnosis is the rule, in peace time at any rate, and in civil urban practice the same should hold good. In time of war, cases of bloody diarrhœa were often treated in forward areas by emetine injections, often with ambulatory patients, and although this was at times unavoidable it was undoubtedly responsible for reducing the vitality of men who were not suffering from amœbic dysentery.

In civil dispensary work more might be accomplished than is, in the way of microscopic diagnosis, though the facilities which exist at present in India for the training in microscopic work of the all-important medical subordinates are admittedly inadequate to fulfil the demands for such training.

In rural private practice amongst the poorer classes microscopic examinations are rarely carried out and blind and tentative treatment of patients passing blood and mucus may have to be condoned but, as a general rule, it is fair to say that the practitioner who administers emetine without having obtained microscopic evidence of the presence of the *Entamœba histolytica*—in whatever phase—in the stool, probably does his patient more harm than good.

The writer's own practice has been to admit cases of dysentery, however slight, to hospital, whenever possible, in order that an accurate diagnosis might be made.

This has been easy, as a large proportion of one's practice has been amongst the military population, but in civil and private practice, and especially in attending the wives and families of officers and officials in stations where no suitable

hospital accommodation existed for their reception one has had, of necessity, to carry one's own microscope to the house of the patient concerned. The stool has then been examined a few minutes after it has been passed.

It is a common practice to send samples of stools to the nearest laboratory in cigarette tins or similar receptacles and to hope to get a reliable report. Unless, however, means are adopted to ensure the maintenance of the fæces at a suitable temperature the results in the majority of cases are nearly worthless.

My colleague, Major J. B. Hance, I.M.S., informs me that he obtains satisfactory results in a considerable proportion of cases by instructing the patient to put a sample of a freshly passed stool into a slightly warmed cigarette tin which is then placed in a larger tin containing warm water, forming a hot water jacket. The whole is then sent by swift messenger to the laboratory where it is placed in a warm incubator until the time of examination. A warmed thermos flask is, of course, the ideal means of transmission to the laboratory, with the fæces in a test tube which is wrapped in cotton-wool to obviate breakage of the flask.

The excellent arrangement which prevailed in Mesopotamia whereby the officer in charge of the hospital laboratory had also charge of the dysentery wards was almost ideal and tended to prevent the arrival in the laboratory for examination of cold, stale fæces.

The diagnosis of amœbic dysentery having been made, the patient should be kept in bed and made to use a bed pan during the whole course of treatment with emetine. This is not only necessary in order to afford rest to the ulcerated gut, as pointed out by Majors Acton and Knowles, but is further most essential in order that as little damage as possible be done to the cardiac mechanism.

The specific action of emetine on the cardiac mechanism is not sufficiently realised, as one is constantly meeting with cases treated in an ambulatory or semi-ambulatory fashion.

This is notably the case with better class patients in both military and civil practice.

The soldier or sepoy can be ordered off to hospital with impunity, but one finds great reluctance on the part of busy military and civil officers and officials, especially seniors, and amongst business men to lie up, with the result that there is often a tendency to treat mild attacks of amœbic dysentery without the patient being sent to bed.

One has, as a result, come across quite a number of cases during the past few years, of post-emetine debility, the patients concerned becoming profoundly debilitated and neurasthenic, with flabby, dilated hearts, rapid, irregular and easily compressible pulses and requiring prolonged rest in order to restore even partial health.

One case, indeed, came to my notice not long ago in which an athlete was permitted to enter and compete in a series of strenuous athletic

events in the hills whilst undergoing ambulatory treatment with emetine injections at the hands of a well-qualified and experienced civil practitioner.

One was not surprised when the competitor referred to confessed to "feeling like death" shortly after the commencement of the tourney, and an ashy-gray colour and shortness of breadth, obvious to all around, were plain evidence of cardio-vascular poisoning.

One can also remember the cases of two patients who suffered severely from post-emetine toxæmia and in whom from the very beginning the condition (amoebic dysentery) had never been shown definitely to exist.

The sword of Damocles, in the shape of a civil suit for damages, which nowadays hangs over the head of every practitioner in the United Kingdom who undertakes the treatment of fractures without x-ray control, may very shortly dangle over those in India who treat dysentery without microscopic control, and sooner or later the fall is bound to come.

A LECTURE ON BLOOD SUGAR AND SUGAR TOLERANCE.

By S. L. BHATIA, M.C., M.A., M.D. (Cantab.),

CAPTAIN I.M.S.,

Professor of Physiology, Grant Medical College, Bombay.

ALL the sugars and starches of the food after digestion in the intestine are absorbed into the blood in the form of monosaccharides, chiefly glucose, partly lævulose and galactose. The bulk of the ordinary diet of human beings, especially in the tropical and subtropical countries, consists of various carbohydrates. On rough estimation it is believed that they form, about two-thirds or even more of the entire diet. Besides the carbohydrates about 60 per cent. of the protein amino-acids and about 10 per cent. of fat are converted into glucose in the course of metabolism. Glucose is ultimately oxidised into CO_2 and water and furnishes the greater part of the energy which is manifested in the shape of muscular work and production of heat. The metabolism of glucose thus represents one of the most important reactions taking place in the animal body.

In this paper I propose to deal briefly with

(a) Concentration of glucose in blood in a normal human being, and the changes that occur before and after taking food;

(b) The relationship that exists between the sugar of blood and of urine;

(c) The alteration of blood sugar that occurs in disease.

METHODS FOR THE ESTIMATION OF BLOOD SUGAR.

All the methods depend on the reducing properties of glucose. They can be divided into two groups—

(a) *Titrimetric group*: in which the reduction of cupric to cuprous oxide in alkaline solution is determined by titration of the latter. Bertrand's, Bang's and Maclean's methods, with their numerous modifications belong to this group.

(b) *Colorimetric group*: in which the production of red colour by reduction of picric acid to sod. picramate in the presence of sod. carbonate is determined by means of a colorimeter, e.g., Benedict's method.

In all my experiments I have employed Maclean's method for estimation of blood sugar for 0.2 c.c. of blood. Blood is deproteinised by heating in an acid saline solution, and the protein is removed by filtration after addition of dialyzed iron. The sugar is estimated in the filtrate by boiling with alkaline copper solution. The quantity of cuprous oxide formed is determined iodometrically.

Colorimetric methods, such as Benedict's, generally give higher results than Maclean's. This is probably due to the fact that the results by these methods include substances other than glucose, such as creatinine. All methods, however, are fairly serviceable, but the great point is to stick to one method, when once adopted, if reliable results are to be obtained. For accurate work Maclean's method is to be recommended. One of its great advantages is that only a very small quantity of blood readily obtained by a fingerprick is needed for estimation, and the samples can be obtained at frequent intervals without much discomfort to the patients.

PERCENTAGE OF SUGAR IN BLOOD.

The sugar content of blood is markedly affected by the intake of food, specially that rich in carbohydrates. It is therefore necessary to estimate it either in the morning before breakfast, or 3 to 4 hours after the last meal to prevent any discrepancies. This is regarded as the normal "fasting" level of blood sugar, which remains remarkably constant in health, and lies between 0.07 per cent. and 0.12 per cent., the average figure taken as a standard for comparison being 0.1 per cent.

After administration of 50 grms. of glucose or intake of rich carbohydrate diet, the blood sugar rises, reaching a maximum in half to one hour, and then declines, till it reaches its former basal level of 0.1 per cent. in $1\frac{1}{2}$ to 2 hours. In normal adults the maximum level reached is 0.17 per cent. Spence (1921) has shown that in children under 3 years of age the rise in blood sugar is very much less marked.

In children over 3 years of age the blood sugar curve is like that of an adult. There are no differences between the two sexes as regards blood sugar.

In old age the curve is prolonged. In healthy persons over 60 years, the high level of blood sugar, i.e., 0.13 to 0.14 per cent. may be maintained for 2 hours or more, before it tends to return to its normal level.

The maximum level of 0.17 or 0.18 is regarded as the threshold value of sugar, for if the amount exceeds this level glycosuria occurs. Maclean and his co-workers insist that in healthy subjects with normal kidneys no excretion of sugar takes place until the concentration in the blood reaches about 0.18 per cent., and it is difficult or impossible to produce a concentration beyond this level.

These figures are based on the estimations made by European and American workers on the blood of persons who habitually live on a mixed diet of meat and vegetables. In India the dietary of the majority of the population differs markedly from that in western countries in that it consists almost entirely of different varieties of carbohydrates. In order to ascertain the normal blood sugar value of Indians and their tolerance for sugar, Coelho and I have worked together in the Physiological Laboratory for some time and a paper based on our observations is now under publication. I shall quote here in some detail some of the data we have obtained and the conclusions arrived at.

EXPERIMENTAL.

The normal blood sugar and sugar tolerance test were determined in vegetarians and non-vegetarians. Altogether 38 individuals between the ages of 17 and 40 were examined, of whom 26 were medical students, 2 members of the teaching staff, and 10 laboratory servants. They were all normal individuals doing their ordinary work. Of these 18 were vegetarians and 20 non-vegetarians. There was much difficulty in dividing them into these two categories, for all Indians partake of large quantities of carbohydrates. Even those who are not strict vegetarians do not take meat habitually, and on the average not oftener than once a day.

For the sugar tolerance test, as suggested by Maclean, 50 grms. of glucose dissolved in 150 c.c. of water were given by mouth. Blood sugar was estimated at half-hourly intervals for 2 hours after the administration of glucose. Urine was examined at one-hourly intervals after the administration of glucose. In some cases 50 grms. of cane-sugar were given instead of glucose. The experiments were performed either in the morning (i.e., after the night's fast) or in the afternoon about 4½ to 5 hours after the last meal.

1. *Non-vegetarians.*—The average blood sugar of 18 individuals was 0.116 per cent., the extremes being 0.083 and 0.147 per cent.

2. *Sugar Tolerance Test.*—15 individuals were given 50 grms. of glucose and 3.50 grms. of cane-sugar. In all cases this was followed by a distinct and rapid rise of blood sugar.

(A) *First 15 individuals:*—

Average blood sugar at the end of ½ hr.	was	0.148%
" " " " " " " " 1 "	"	0.146%
" " " " " " " " 1½ hrs.	"	0.122%
" " " " " " " " 2 "	"	0.114%

Speaking generally, the blood sugar reaches a maximum from half to one hour after glucose,

and then shows a decline. At the end of 2 hours in 9 cases it was actually below the pre-glucose level. In 2 cases the difference was 0.001 or 0.002 per cent. which is negligible. In the remaining 4 the amount was still above the normal. Of these, 2 had a distinct glycosuria at the end of the first hour.

The maximum rise in the blood sugar in this series was 110 mgm. and the lowest 13 mgm., the average being 49 mgm.

(B) *Last 3 persons*, who were given cane-sugar, had all a high blood sugar level to begin with. The maximum rise in the blood sugar was 99 mgm., and the lowest 25 mgm. Except in one case, the blood sugar remained high at the end of two hours. All these three cases had glycosuria.

VEGETARIANS.

1. *Blood Sugar.*—The average blood sugar of 20 individuals in this series was 0.149 per cent., the extremes being 0.084 per cent. and 0.242 per cent.

This figure is much higher than that obtained from the non-vegetarians. It was observed that estimations made in the morning before breakfast gave a lower figure than those made in the afternoon about 4½ hours after the morning meal.

2. *Sugar Tolerance Test.*—7 were given 50 grms. of glucose, and 13, 50 grms. of cane-sugar.

(A) 7 persons, given 50 grms. of glucose.

Average blood sugar at the end of ½ hr.	was	0.140%
" " " " " " " " 1 "	"	0.137%
" " " " " " " " 1½ hrs.	"	0.109%
" " " " " " " " 2 "	"	0.104%

The blood sugar showed a rise, which reached a maximum in 30 to 60 minutes after glucose. This was followed by a decline. At the end of 2 hours, in 4 out of 7 cases, the blood sugar came down to the pre-glucose level. In the remaining 3 it was still higher than before. The maximum rise varied in different individuals. The average figure for 7 individuals is 47 mgm., the extremes being 84 and 12 mgms. respectively.

(B) In the remaining 13 cases, who were given cane-sugar, there was likewise a rise in blood sugar followed by a decline.

Average blood sugar at the end of ½ hr.	was	0.209%
" " " " " " " " 1 "	"	0.189%
" " " " " " " " 1½ "	"	0.177%
" " " " " " " " 2 "	"	0.158%

In all these cases the initial blood sugar was comparatively high. At the end of 2 hours, in 5 persons, it came down to the pre-glucose level or lower.

In two others the difference was of 2 or 5 mgms., which is negligible. In all the remaining 6, the difference was quite marked, ranging from 12 to 38 mgms. above the pre-glucose level.

The maximum rise varied considerably between 127 mgms. and 2 mgms. If it is permissible to arrive at an average figure from results which

vary so much, the average rise would be about 48 mgms.

SUGAR IN URINE.

I. Non-vegetarians.—Of 18 non-vegetarians, 4 had a trace of sugar in the urine prior to the test. After taking 50 grms. of sugar (glucose or cane-sugar), in addition to these 4, which continued to show glycosuria, glycuressis occurred in the other individuals also. Thus 5 fresh individuals showed glycuressis one hour after taking sugar, and 2 showed the same after 2 hours, their urine originally having been sugar-free. The quantity was not very large, ranging from 0.1 per cent. to 0.8 or 0.9 per cent.

II. Vegetarians.—Amongst the vegetarians, in 10 out of 20 in our series the urine showed a trace of sugar. The urines passed in the morning before breakfast were generally sugar-free, but in the same individual, if the urine was tested in the afternoon some hours after breakfast, a trace of sugar was often seen to be present. One hour after the administration of sugar the urine contained traces of sugar in 15 individuals, of whom 5 were those whose urine was originally sugar-free.

After 2 hours, 12 still showed a trace. This persistence and frequency of glycuressis amongst vegetarians is very significant. The sugar tolerance test indicates that in both vegetarians and non-vegetarians in our series the renal threshold for sugar was comparatively low. Amongst non-vegetarians, in all, except two whose blood sugar rose above 0.142 per cent., there appeared a trace of sugar in the urine. Amongst vegetarians the renal threshold is also in the neighbourhood of 0.143 per cent. The glycuressis was commoner in vegetarians. It would seem as if persistent ingestion of a rich carbohydrate diet lowers the threshold value of sugar.

This leads us to the consideration of the source of blood sugar and the manner of its disposal in the body.

The addition of glucose in the blood is the result of

- (a) Absorption from the intestine;
- (b) Hydrolysis of glycogen (glycogenolysis), especially in the liver and partly in muscles;
- (c) New formation of glucose out of non-carbohydrate material, namely, amino-acids, etc.

Disappearance of glucose in the blood is the result of

- (a) Oxidation in the tissues;
- (b) Excretion by the kidneys;
- (c) Conversion into glycogen, and its storage, as such in liver and muscles;
- (d) Conversion into non-carbohydrate, such as fat.

All these factors do not act to an equal degree in regulating the normal sugar content of the blood. When 50 grms. of glucose is administered to a healthy adult, blood sugar rapidly rises but does not increase beyond a certain level, and the agencies responsible for subsequent fall may

be either oxidation, excretion, or conversion into glycogen. Increased oxidation does take place to a certain extent. It has been estimated by Sanger and Hun that the excess of sugar thus oxidised during 2½ hours after intake of glucose accounts only for 18 per cent. of sugar. The main factor, however, is the storage of glucose in the liver and tissues as glycogen. Sugars which are poor glycogen formers (such as galactose) produce a much higher rise in blood sugar than glucose. On the other hand, lævulose, which is a good glycogen former, when administered produces no rise of sugar in peripheral blood if the liver is functioning normally, for the reason that it is rapidly and completely converted into glycogen.

Another significant fact which supports the storage hypothesis is that the sugar tolerance curve obtained from venous blood is lower than that from arterial blood, as obtained by finger-prick. This diminution represents the loss of blood sugar after the blood has circulated through the tissues. This loss is due to storage in muscles, which contain more than half the glycogen content in the body. This storage mechanism is at its height when the blood sugar is rapidly falling after the first hour. It is found that a second dose of glucose during this phase of active glycogenesis does not produce a second rise in blood sugar. In some individuals, however, it may produce a slight rise, but it never reaches its former maximum level.

"THRESHOLD" VALUE OF SUGAR.

Recent research has clearly established that normal urine contains traces of sugar. Benedict, Osterberg and Neuwirth (1918) have shown that in an apparently healthy person having no diabetic tendency, as much as 0.6 per cent. of sugar may be present after a breakfast rich in carbohydrates, and in 24 hours the total sugar passed in urine may amount to 1.586 gm. (0.184 per cent.). If the same person is given an ordinary mixed diet, the total sugar eliminated may approximate to 1 gm. per day. The output of sugar in urine after a meal follows a curve similar to that of blood sugar, but slightly delayed in time. In both, there is an increase followed by a decline. There is a close relationship between the percentage of blood sugar and sugar in urine. Benedict has even shown that each meal is followed by a rise in urinary sugar irrespective of the nature of the diet, suggesting that ordinary digestive processes have an accelerating effect on glycogenolysis.

Now, when blood sugar reaches a level of 0.18 per cent. abnormal traces of sugar appear in the urine. This threshold value of the normal kidney is not easy to account for. Certain experiments by Hamburger are of interest in this connection. He performed certain perfusion experiments on frog's kidney, and came to the conclusion that glucose occupies a peculiar position among isomeric monosaccharides with regard to glomerular epithelium, suggesting the relation

of a key to a lock. According to him the configuration of the glucose molecule gives to it those peculiar properties which cause it to be retained in circulation by a healthy kidney. He further found that the permeability of glomerular epithelium for sugar could be diminished or increased in experiments with frog's kidney perfused with Ringer's solution, if the proportion of inorganic constituents in the perfusion fluid were altered. In this respect, the concentration of free calcium ions and sod. bicarbonate are important factors. When free calcium ions reached a certain concentration the kidney became impervious to glucose, but when this was altered it became permeable. It was also found that in the absence of sod. bicarbonate, the kidney became very permeable and no glucose was retained. As regards the permeability of the kidney to dextrose, calcium and sodium seem to have opposite effects, and it follows that the composition of the blood as regards calcium and sodium, and also its acid-base equilibrium are important factors in sugar excretion. Now, this threshold value which is regarded as 0.18 per cent. is distinctly low in the majority of the subjects of our experiments. It seems to be in the neighbourhood of 0.15 per cent.

HYPOGLYCÆMIA.

1. *Renal Glycosuria*.—In the condition known as renal glycosuria it is said that there is an increased permeability of the kidney to glucose, that with a normal blood sugar level glycosuria occurs, and this is ascribed to the low "threshold value" of sugar. Such cases do occasionally occur.

The urine may contain even 2 per cent. of sugar when the blood sugar content is less than 1 per cent. The usual symptoms of diabetes are absent. If Hamburger's hypothesis regarding the renal permeability to glucose be accepted, this condition would be due to a low percentage of calcium in the blood. Cammidge records certain cases in which there was a diminution of calcium content of the blood in such cases. This has an important bearing on treatment. Such cases of renal glycosuria have been treated by Cammidge by allowing ordinary mixed diet, gr. 1|10 parathyroid nightly, and 5 grs. of calcium chloride three times a day after meals, with some improvement. It might be pointed out that in dealing with this condition great care should be taken not to confuse it with early cases of true diabetes.

2. *Hypoglycæmia resulting from Insulin Injection*.—An injection of insulin in diabetic or normal subjects is followed by an immediate fall in blood sugar, reaching its maximum in 2 to 4 hours. With intravenous injections the effect is very rapid, but with subcutaneous the duration is variable. The degree of hypoglycæmia which is attended by definite symptoms depends on individual idiosyncrasy. The symptoms may arise in one case with blood sugar of 0.07 per

cent., in another not until it has fallen to 0.035 per cent. As a rule, however, when blood sugar has fallen to 0.035 per cent. the person becomes unconscious. Initial symptoms are sweating, nervousness, flushing, tremulousness and rapid pulse, also excitement, and delirium developing into coma. In rabbits convulsions occur, but not as rule in men. These symptoms can be rapidly cured by a dose of glucose together with an injection of epinephrin.

3. *Hypoglycæmia resulting from injury to the liver*.—When the liver is cut out from the circulation, symptoms of muscular weakness, twitching, generalised convulsions and death supervene. Blood sugar falls, and symptoms make their appearance when its level is 0.04 per cent. The condition is relieved by administration of glucose.

4. Renal threshold for glucose is lowered in early diabetes and in early pregnancy.

HYPERGLYCÆMIA.

1. *Diabetes Mellitus*.—In this condition, which is due to damage to cells of the islets of Langerhans (B. cells) of the pancreas, the highest known percentage of blood sugar is met with. The average percentage in mild cases is 0.3 to 0.4 per cent. but I have records of a case showing over 0.6 per cent. The maximum record is 0.7 to 0.8 per cent. The capacity for storing and oxidising carbohydrate is diminished. In all cases of glycosuria whose true cause is not evident, it is essential to estimate the blood sugar and carry out the sugar tolerance test, as already described. This will give evidence of hyperglycæmia, and the curve characteristic of this disease. If 50 grms. of glucose is given to a case of diabetes, the blood sugar rises slowly and the rise is much prolonged, reaching a level not met with in a normal individual. The return of blood sugar is also very slow, and the total duration of hyperglycæmia is much greater than in health, lasting up to 3 or even 4 hours.

Blood sugar rises above the renal threshold and definite and marked glycosuria occurs. So in diagnosing a case of diabetes, the height and duration are both important, especially the latter. In early cases, the characteristic feature is the slow descent. It will be obvious that estimation of urinary sugar does not alone give the desired information.

2. Hyperglycæmia is met with in many diseases of ductless glands:—

(a) *Thyroid gland*.—Removal of the thyroid gland leads to diminution of blood sugar, and reduces hyperglycæmia, produced by removal of the pancreas. Thyroid feeding in normal animals diminishes tolerance for carbohydrates and blood sugar is raised. The respiratory quotient is raised indicating increased combustion.

Glycosuria is often a symptom of exophthalmic goitre. There is diminished tolerance for carbohydrates in hyperthyroidism, and this is due largely to defective storage mechanism.

In thyroid deficiency sugar tolerance is variable. In cretinism it is increased; in myxoedema it may be either increased or diminished, but the renal threshold is generally raised.

(b) *Parathyroids*.—Removal of parathyroids leads to a reduction of sugar tolerance.

(c) *Pituitary body*.—Injection of the active principle of the posterior lobe results in hyperglycaemia; extracts of the anterior lobe have no such effect.

Acromegaly.—In this disease also hyperglycaemia and glycosuria are as a rule developed. In fasting the blood sugar may exceed 0.3 per cent.

Hypopituitarism.—(Frolich's disease).

This condition, as regards blood sugar, resembles hypothyroidism. Increased tolerance for sugar is generally observed.

(d) *Suprarenals*.—Injection of epinephrin leads to a rise in blood sugar. This is due to an increased discharge of glycogen and its conversion into glucose in the liver. Epinephrin is antagonistic in its action to insulin and in hypoglycaemia, after insulin injection, an injection of epinephrin may be given. Speaking generally, hyperactivity of the thyroid, pituitary and adrenals produces hyperglycaemia and a fall in sugar tolerance.

3. Hyperglycaemia and diminished tolerance for sugar may be met with in various infective conditions. This is usually of a transitory nature. In anaesthesia with chloroform or ether and in asphyxia there is also a rise of blood sugar. Occasionally in obesity there is diminished tolerance for carbohydrates. In chronic interstitial nephritis, arterio-sclerosis and hyperpiesia, blood sugar may be high, the renal threshold may be raised, and no glycosuria. Attention has also been drawn recently to the fact that in gastrointestinal cancer there is high blood sugar and a prolonged sugar tolerance curve.

4. *Alimentary Hyperglycaemia*.—I wish to draw your attention to this condition, which is of peculiar importance to us, since in our experiments the main point brought out is that there is a marked rise of blood sugar in pure vegetarians after glucose injection, and that this is associated with glycosuria.

The liver plays a part of the first importance in carbohydrate metabolism, but in the production of glycosuria its role is considered of secondary importance. If a person takes excess of carbohydrates in his diet, as most of us do, the glycogenetic function of the liver may be strained too much and a portion of the sugar absorbed from the intestine may pass into systemic blood and thus produce hyperglycaemia and glycosuria. This seems to be the most likely explanation of the frequency of glycosuria in this country. In the early stages there may be no damage to the islets of Langerhans, but merely a deficiency of the storage mechanism. Apart from flooding the liver with products of carbohydrates of the diet, alimentary hyperglycaemia may occur if there is any congenital or acquired defect in the glycogenic function of the liver.

Such factors, I have no doubt, operate very frequently in this country, where so many diseases occur which throw a strain on the liver. I am sure the frequency of glycosuria in this country is due, to a very large extent, to a rich carbohydrate diet and sedentary habits of life, which impair the glycogenic function of the liver. The activity of the cells of the islets of Langerhans are thus overstrained for a long time. The pancreas eventually breaks down, producing the well marked clinical condition of diabetes mellitus.

The few observations recorded here give strong support to this view. Benedict, Osterberg and Neuirth's experiments show that the normal adult human being does not possess a complete tolerance for sugar, and the difference between a normal and diabetic person is purely a quantitative one. We should all do well to follow their advice to observe caution in the use of sugar with our meals.

Certain observations by Macleod show that excess of cane-sugar in the diet may be followed by the absorption of cane-sugar as such in the blood, which may escape storage in the liver, causing the presence of cane-sugar and also invert-sugar in the urine. Alimentary glycosuria is particularly evident when sugar is taken without any other food. He says that cane-sugar was given in an amount corresponding to 5 grms. per kilogram body weight to 17 healthy individuals. In $1\frac{1}{2}$ hours afterwards the urine of 10 of these individuals contained cane-sugar, 3 containing dextrose and laevulose also. It was found that cane-sugar continued to be excreted for about 7 hours. Coelho and I have also noticed that 50 grms. of cane-sugar causes in some cases a higher rise of blood sugar than glucose, but the curves obtained with cane-sugar are not so regular and uniform as with glucose.

The observations recorded here are limited, and further work is necessary to elucidate many problems connected with this complicated subject. I might suggest the following lines on which this work might be carried out:—

1. To make quantitative observations on the diets of vegetarians and non-vegetarians, and to ascertain the incidence of hyperglycaemia and glycosuria in relation to the amount of carbohydrate ingested.

2. To keep a non-vegetarian on a purely vegetarian diet for some time and to ascertain the changes in blood sugar and sugar tolerance that may occur.

3. To ascertain the functional efficiency of the liver in vegetarians and non-vegetarians as to its capacity for glycogen formation.

I believe work on these lines will furnish us with valuable data which may eventually lead to a more hygienic way of regulating our dietary. The moral of it is that we should eat less starch and sugar and take more physical exercise.

BACTERIOLOGICAL STUDY OF STOOLS OF 746 CLINICAL CHOLERA CASES IN CALCUTTA.

By G. C. MAITRA,

CAPTAIN, I.M.S.,

Research Worker, Calcutta School of Tropical Medicine and Hygiene

(Mining Association Endowment)

and

J. B. BASU, M.B.,

Assistant Research Worker.

IN 1923, while investigating the origin of cholera epidemics in the Jharia coal-fields, one of us (Maitra, 1925) came across a series of cases which in general symptomatology and clinical features could not be distinguished from cases of true cholera confirmed by laboratory findings. But when the stools of such cases were examined bacteriologically they gave persistently negative results and thus stood in marked contrast to another group of cases investigated in the same field almost about the same time. In the latter group Koch's comma vibrios were found to be the etiological factor and were isolated from all cases without much difficulty.

As all these cases were investigated in most adverse circumstances under field conditions, it was reasonably supposed at the time that the failure to ascertain the etiology might have been due to some fault in technique or in the media employed in the observations.

Subsequently, however, when opportunities were available and literature on the subject was consulted it was found that considerable confusion existed regarding the etiology of cases of clinical cholera. Stanton (1917) working in the Federated Malay States found and described, *Vibrio cholerae*, *B. dysenteriae* Shiga, *B. enteritidis* Gärtner, *B. faecalis alkaligenes*, *B. proteus*, etc., in connection with cases of clinical cholera which caused a considerable flutter in official circles and led to the appointment of a Government Commission in the latter part of 1916. Greig (1917) in the course of his continued observations in the Calcutta Medical College Hospital, extending over 4 years, found only

cholera and cholera-like vibrios associated with cases of clinical cholera. Rogers (1921) mentioned among other things that *B. dysenteriae* Shiga could give rise to similar conditions and that the fact could only be ascertained by a careful bacteriological examination of the stools. Sprawson and Mukherjee (1922) investigated a choleroïd epidemic in Lucknow in 1921 and isolated a paratyphoid B-like organism from the stools of about 60 per cent. of cases. This organism when isolated fresh did not, however, agglutinate with the high titre paratyphoid B-serum even in a dilution of 1 in 10. Cunningham (1923) also mentions similar cases in association with Shiga infection.

These findings of previous workers coupled with our own experience in the coal-fields in 1923 made it justifiable to repeat the observations in the Campbell Hospital, Calcutta, where laboratory facilities and abundant materials for study existed side by side.

Our observations were commenced in the beginning of 1924 when suspected cholera cases were just beginning to appear in the city and were carried on to the end of the year. The stools were studied not only culturally for the isolation of specific organisms, but their physical characters and the results of microscopical examination of both stained and unstained preparations for parasitic and tissue elements were recorded at the same time. The technique employed was an immediate and direct plating of the fresh sample collected under our own supervision, followed by a secondary plating after 4 hours of enrichment in peptone medium. For direct plating both McConkey's agar and bile-salt agar were employed. For plating after enrichment bile salt agar alone was used. The latter medium consistently yielded the better and more reliable results in our hands for the cultivation and isolation of cholera and allied vibrios. Suspicious colonies from plates were sub-cultured and tested for identification by various cultural, biochemical and serological methods.

Out of a total of 746 cases examined 597 yielded the following cultural results:—

Cholera and allied vibrios	.. 590
Non-lactose-fermenting organisms	.. 4
Short chained streptococci	.. 3

In the remaining 149 cases although the cultural results were negative, the results of microscopic examination were significant and interesting. The results are summarised in the following table:—

Vibrios.	Exudate of Choleraic type.	Exudate of bacillary Dysentery type.	Entamoeba histolytica.	Charcot Leyden Crystals.	Negative.
40	46	4	1	1	57

In a previous article (1925) the significance of the histopathological elements of stools in the diagnosis of cholera has been dealt with. It follows therefore that no less than 86 of the cases in the culturally-negative series were due to vibronic infection.

A combined consideration of the cultural and microscopical results therefore shows that of 746 cases of clinical cholera 90 per cent. of the total were caused by *V. cholerae* or allied vibrios. Most of the negative findings were associated with cases where the stools had become faeculent and when the chances of recovering the causal organism had in consequence fallen to a minimum. Even in these cases it is reasonable to conclude that vibrios played the same rôle and in the same proportion as in the positive cases.

As regards the rôle of non-lactose-fermenting organisms of the dysenteric and food-poisoning group in the production of clinical cholera we are quite convinced of their unimportance in the Calcutta series of cases. Although these organisms were seldom cultivated their cultural and serological characters were undefined and variable.

CONCLUSIONS.

1. Ninety per cent. of cases of clinical cholera investigated in Calcutta were associated with vibronic infection as proved by cultural and histopathological findings.

2. Cases of the negative series would have shewn vibrios in the same proportion had it been possible to examine them in time.

A NEW ORGANIC ANTIMONY COMPOUND FOR THE TREATMENT OF KALA-AZAR.

By L. E. NAPIER, M.R.C.S., L.R.C.P.,

Kala-azar Research Worker (Indian Tea Association Endowment), Calcutta School of Tropical Medicine and Hygiene.

THE success of organic compounds of antimony, stibosan and urea-stibamine, in the

treatment of kala-azar makes it probable that manufacturing chemists in the near future will endeavour to produce other similar compounds with equal, if not greater, leishmanicidal properties. The main advantage of these organic compounds over the simpler antimony salt is that as the relative toxicity of the former is very low they can be administered in much larger doses than the latter.

During the last few years I have tested the relative toxicity and curative properties of a number of these compounds. Recently I was approached by a firm of manufacturing chemists, the Union Drug Company, Ltd., Calcutta, who had prepared a new antimony compound and wished me to test it therapeutically.

The Compound.—The compound was supplied to me in sealed ampoules, labelled "Aminostib-urea"; each ampoule contained 0.1, 0.15 or 0.2 grammes. The preparation is in the form of a fine light brown powder which is easily soluble in water forming a brown coloured solution; it is said to be a combination of para-amino-phenylstibinic acid with urea and glucose and to contain 24.8 per cent. metallic antimony.

The Toxicity.—It was not convenient to test the toxicity of this compound very accurately at the time, but before using it therapeutically I made a rough estimate of its toxicity in mice and found that the majority survived an intravenous injection of 225 milligrammes per kilogramme weight of body; the toxicity is therefore in the region of that of the two compounds referred to above.

Treatment of Cases.—Altogether seven cases of kala-azar in the Carmichael Hospital for Tropical Diseases were treated with this compound. The initial dose, except in the first case treated and in the case of the child, was 0.1 gramme; subsequently 0.2 gramme was given. The child received an initial dose of 0.05 gramme and subsequent doses of 0.1 gramme. The injections were given intravenously three times weekly; a 5-per cent. solution in sterilised distilled water was used. Details of the cases and the results of treatment are given in the table below. In every case the diagnosis was confirmed by spleen puncture and in every instance in order to confirm cure either a spleen or liver puncture was performed 10 days after the last injection and the material placed on N.N.N. medium which was kept in the cool incubator for at least 14 days. Cases 1 to 5 had never received any antimony treatment before their course of injections with this compound was begun, case No. 6 had received "80 injections of antimony tartrate and a full course of urea-stibamine" and case No. 7 had received a full course of urea-stibamine and a full course of stibosan. The two relapsed cases had not received any injections within 6 weeks of their admission to hospital and were both running a high remittent type of temperature.

Result of Treatment.—The first six cases were apparently cured but the last case, although

P.=palpable, i.e., level with costal margin, but not protruding below it

clinically vastly improved, still showed a Leishmania infection by spleen puncture. No vomiting or other untoward symptoms were noted after the injections. Case No. 5 was febrile throughout the whole course of the treatment but her temperature fell to normal immediately the injections were discontinued. The temperature fell to normal with remarkable rapidity in cases Nos. 1, 3 and, in view of the fact that this was obviously a resistant case, No. 6.

Comment.—It is quite impossible to gauge the relative value of "aminostiburea" in the treatment of kala-azar, on a trial on such a limited number of cases, but it would appear that this compound is in the same class with stibosan, urea-stibamine and certain other organic antimony compounds. It is obviously a compound which is worthy of a more extensive trial.

My thanks are due to the Union Drug Company for a generous supply of "aminostiburea."

SOME NOTES ON LATRINES AND HOOKWORM INCIDENCE ON AN ESTATE, AS DIAGNOSED BY THE CLAYTON-LANE CENTRIFUGE.

By RONALD SENIOR-WHITE, F.E.S.,
Malariaologist, the Kepitigalla Rubber Estates, Ltd.,
Matale.

THE estate to which the following notes apply is in most respects typical of company-owned estates in the island of Ceylon. It seems probable, therefore, that the publication of figures showing the incidence of ankylostomiasis eight years after the Rockefeller Commission commenced work in the island will be of interest to those working on the disease.

Prior to the commencement of the Commission's campaign the estate, in common with practically every other such, provided no latrine accommodation for its labour force, who resorted for purposes of nature to the area around their lines,

as was only too apparent to the nose when in the vicinity of the latter.

With commencement of work by the Rockefeller Commission the provision of latrines was enforced by law. On the estate in question these were constructed over pits dug in laterite soil to a depth of sixteen feet, their sides being practically vertical and, after the first few feet,—varying with top-soil depth in individual spots,—of a hardness nearly comparable with a chalk pit in England. The buildings themselves were of tarred weather-boarding, with corrugated iron roof, the squatting places being also of board, which was re-tarred at suitably frequent intervals. Each pit served four to six actual squatting places, the two sexes being accommodated on separate sides of a central wall. To each side a cement-floored ablution cubicle, draining into the pit, was provided, and cemented invert drains caught the roof-water and led it away from the pit. The original cost of such a latrine of four places, including digging the pit, averaged about Rs. 250.

On this estate the latrines are all situated on a steeply-sloping hillside, and the pits nowhere struck sub-soil water. They have remained absolutely dry throughout their existence. If such is struck, and the pit contains standing water, *Culex fatigans* will breed freely therein. To this is due the intolerable nuisance found in some of the wetter and more elevated districts of Ceylon, where mosquito nets are now absolutely essential, whereas before the latrine ordinance there was no need for such.

In the process of time, various facts have emerged from experience. The six-place pit is unsuitable. The rate of deposition of faeces has at times exceeded the capacity of bacterial destruction. When this has occurred, the level of the faeces has risen very rapidly, with ensuant bad odours. If a latrine in this state be

temporarily put out of use the level of the deposit will, in a few months, sink by several feet,—but this entails alteration of sanitary arrangements, congestion takes place at the alternative latrines, and soil pollution may commence. This is easily understood when it is remembered that the working coolie has to pass his morning motion in the short space of time after getting up and before proceeding to work, and the latrine capacity on an estate must be capable of accommodating all who need it at that hour of the day. Failure to ensure this will unavoidably result in soil pollution. In practice it has been found that two squatting places for each sex for a set of ten line rooms, (accommodating from twenty to twenty-five persons of over infantile age), is sufficient. One latrine of this size serving twice this number of rooms caused much faecal pollution around the set of lines concerned until it was duplicated.

Lids to the holes in the squatting places, self-closing by gravity, were originally provided. These proved unsatisfactory. The coolie usually fouls the squatting place around the hole, and when the lid falls back on the mess it is in no state to come into contact with the back of the next user. The latter, therefore, either defecates on the lid, or the place remains out of use until cleaned by the sweeper. On this estate each sweeper has charge of about forty line rooms and their sets of latrines, which has been found to be about the maximum task possible with the high standard of sanitation enforced.

The coolie, therefore, usually broke off the wooden attachment to the lid which prevented it passing the vertical, and propped it back. A distressing fatality due to trust in these lids being in place occurred in consequence, a child running into a latrine to look for its mother, but entering the men's side by mistake, having fallen down an uncovered hole. Now that the parents know that no lids to the holes exist, they are naturally careful not to allow infants to toddle round the latrines. The actual holes also are somewhat smaller in later constructions, but as the squatting places in such are of reinforced concrete the extra amount of fouling at the edges of the holes is not of great importance, as deposit can be washed into the pit before use from the chattie every coolie carries on errands of nature. In later constructions also arrangements have been made to admit more light than in the first pattern, in which darkness was aimed at to discourage flies. This point has been found unnecessary. Examination of the surface of the semi-liquid mass of faeces in the pits by means of a torch has at times revealed a crawling mass of larvæ, mainly those of *Chrysomyia megacephala* Fb., adults of which have been noticed resting on vegetation around the latrines,* but no fly

nuisance has ever resulted. The explanation would seem to be that the larvæ must find dry loose earth for pupation, and such is not available above the mass on the hard, nearly vertical sides of the pit. The prepupal larvæ therefore, I think, perish. Oviposition must have been by eggs dropped into darkness for several feet. I do not think that any fly would descend into the pit itself, and on various torch examinations I have never noticed adults in the pits.

Naturally the pits must slowly fill up, however efficient bacterial action may be, but out of seven sets erected in 1917-18 it has only been necessary to close two for this reason up to the middle of 1925. One of these was a 6-place set, now replaced by two separate sets of smaller capacity, and the other served twenty rooms as mentioned above. It has also been duplicated. At the moment of writing one more set now requires replacement, the first set of four places serving only ten line rooms to fill up.

It is possible that the periodical rises of level, attributed to over use, are not due to this but to the inhibition of bacterial action by the use of disinfectant. A little of the Cresol compounds used in line sanitation must at times find its way into the pits, but I have never been able to correlate a bacterial upset with the emptying of a quantity of such solution into the affected pit, or the addition by sweepers of unauthorized substances, such as line rubbish containing fermentable vegetable matter, which is said to be a cause of unsatisfactory bacterial action, and I think the original explanation is correct. There is probably a definite ratio between the surface area of a pit and the quantity of faeces that can be successfully dealt with regularly, but I have never attempted to work this out.

Faecal pollution of soil on this estate has been very carefully checked for the last seven years, until now it is ordinarily non-existent. None the less, so ingrained in the Tamil coolie are his filthy habits that the least relaxation of vigilance always results in an outbreak of promiscuous defæcation. Punishment, or the fear of it, alone keeps the latrines in proper use. Such a result can only be achieved on an estate where the labour is under perfect control and is not otherwise discontented. On many estates the latrines exist more to comply with the law than for use.

Turning now to ankylostomiasis itself, the estate in question, in common with most of those in Ceylon, showed an infection rate of 98 per cent. to 99 per cent. by the simple smear method when originally surveyed. Being situate in the district in which the Rockefeller Campaign started operations, the original treatments were given without latrines being installed, and therefore, for at least a year thereafter, re-infection must have occurred copiously. The rainfall on the estate is about 80 inches per annum, most of it in the North-East Monsoon, at which time of year the original treatments were carried out.

*I once watched a *Vespa cincla* preying on them. The flies were motionless with the exhaustion of oviposition and the approach of evening. The wasp caught and ate them one by one, flying to the top of a neighbouring Papaya tree to consume its prey.

Thereafter no routine treatments were made for six years. Bad cases coming from India or other estates were treated soon after arrival by the dispenser, without microscopic diagnosis. In other words, 'bad cases' would mean those showing a noticeable degree of anæmia and œdema,—that is, very bad cases indeed.

The writer brought back with him from leave last year the then newly demonstrated Clayton-Lane centrifuge for ankylostomiasis diagnosis, the first, he believes, to reach the island, and with it a routine examination of every coolie inhabitant of the estate was made. Owing to pressure of other work it was not found possible to carry out the complete Clayton-Lane technique for quantitative results. All that could be done was to take a lump of fæces approximately equal in bulk to 1 c.c. and emulsify it direct in saturated saline, the tube being then filled up till the meniscus stood just above its mouth, the cover slip was applied and the whole centrifuged.

My laboratory boy and a sweeper under the supervision of the estate dispenser formed a gang just sufficient to keep myself at the microscope continuously occupied. The routine of operation was as follows:—

The sweeper opened the sample tins and removed and emulsified the material in about three-quarters of a tube of saline standing each tube as completed in a test tube rack. The dispenser meanwhile moved the opened tin and its labelled lid opposite the corresponding tube in the rack, and filled the latter up to the top. When in the centrifuge bucket he added by a pipette the final amount of saline necessary to touch the cover slip, and applied the same. The laboratory boy worked the centrifuge, carried slides to and from the microscope and washed coverslips. The sweeper washed the centrifuge tubes. Generally four slides, numbered consecutively to agree with holes in the test tube rack, were used. The microscopist quoting the number of the slide under examination, the dispenser identified it with the patient from the label on the tin, and the result was entered. With this staff, doing only qualitative diagnosis, it was found possible to do nearly sixty samples per hour after every one had become used to their duties. Much longer has to be spent on a negative than on a positive slide.

The original treatment by the Rockefeller Commission was made with chenopodium oil,—in the series now under discussion this was used for children, and adults showing ascaris infection, but the chief drug used was carbon tetrachloride. Coolies have no objection to the latter. In fact some negative patients asked for it when those still positive were under re-treatment. It apparently has a somewhat alcoholic effect much appreciated by the coolie. No accidents with it have occurred here. The dosages were indicated by officers of the campaign as usual.

It will be observed that the numbers examined

after the first treatment are less than those of the original examination. This is due to the omission from the former of negatives and those exempted from treatment for the usual conditions. In the fourth examination made a year later every inhabitant of the estate was again tested.

TABLE I.

DATE.	A. 3rd Apl. 1924.	B. 5th Aug. 1924.	C. 18th Sept. 1924.	D. 11th June 1925.

- A. No general treatment since 1917.
 B. General treatment on 3rd July 1924.
 C. Re-treatment of cases still positive on 22nd August 1924 and 4th September 1924.
 D. No general treatment during intervening period.

Analysis of Column D.

	Examined.	Positive.	Negative.	Per cent. positive.	
New coolies ..	29	21	8	72	All heavy.
Old coolies ..	193	94	99	49*	40 per cent. of positives with 1-2 eggs only.
	222	115	107	52	

* Increase over column C due to inclusion of exempted coolies.

One very extraordinary point is brought out by the figures given above, viz., that apparently the more treatment that is done, the higher becomes the incidence of ascaris and trichuris. I am quite at a loss to account for this. The rise in the former after the first treatment, from 3 per cent. to 16 per cent. cannot represent fresh infection occurring in the intervening four months. Can it be that treatment irritates the worms into oviposition? Carbon tetrachloride is said to have no effect on ascaris, and it is not known whether the ascaridol fraction of the chenopodium oil was high. In any case, statistically, the position as regards ascaris is worse at the end than at the commencement of treatment. It was obvious also, when doing the actual examinations, that ascariasis is largely a family infection. This must mean food contamination, and it would therefore appear that special attention to mothers of families who show ascariasis should be undertaken.

As in all labour forces there is a constant in and out movement of coolies, though it is smaller in the case of the estate under discussion than in many known to the writer. The figures of the

last examination have therefore been sub-divided to show new and old coolies separately, the latter being those who were present during the treatments of 1924. New coolies, in this instance, have none of them come direct from India, but all from neighbouring estates, and the incidence among these coolies, in spite of the fact that obviously infected cases were treated on arrival, is nearly double that of the old coolies of the estate, while in every case the amount of individual infection appeared higher. It is to be feared, therefore, that on most estates the ankylostomiasis incidence is still in the vicinity of 70 per cent., a fact which reveals how much has yet to be done before this disease is got under control.

TABLE II.

	SAMOA.		CEYLON.	
	Infected. Per cent.	Reduction Per cent.	Infected. Per cent.	Reduction. Per cent.
Before treatment.	97	—	77	—
After 1st treatment.	59	38	69	8
After 2nd treatment.	37	22	46½	23

Comparing the foregoing table with the figures recently published from Samoa, using the same technique (Hopkins, 1925), we get:

Even allowing that the original reduction in the Ceylon series had been from about 98 per cent., and that, if the first treatment of 1924 had been on virgin ground as in Samoa, the reduction might well have been from that figure down to 69 per cent., we still find that there is less reduction for first treatment in Ceylon than in Samoa. The reductions for the second treatment are practically identical in the two islands, and at the end of it both sets of patients were left with a large amount of residual infection. Probably little of this was economically important to the patients themselves,—and if everywhere proper usage of latrines was in force would have comparatively little importance, but there is no word of the use of latrines in the Samoa paper, and we know that they are very ineffectively used in Ceylon, hence these half-cured cases may not only get more heavily infected themselves, but are still liable to act as disseminators of the disease. The first is likely to be the more important occurrence with many of those treated here, for at the final examination 38 of the 94 positives among the old coolies, or 40 per cent., showed only one or two eggs in the film made from approximately 1 c.c. of stool. These would count as negatives, 'cured,' under any technique less delicate than that of Clayton Lane. This is simple and sure, and even for routine campaign diagnosis an immense improvement on any of the pre-existing ones. I would like however to confirm

Hopkins' remarks about the apparatus. The plating and paint is rapidly and badly attacked by the salt solution, though in my case the aluminium arms have not been affected. The handle also should be of stronger construction for unskilled use. With advantage also the arms might be permanently numbered so as to render tube-tin-slide identification simpler, but these points are all minor blemishes such as invariably show themselves in any new pattern of apparatus, and will doubtless be rectified in later manufacture.

A Mirror of Hospital Practice.

AN INTERESTING CASE OF PERINEAL FISTULA.

By B. R. GARG, L.M.P.,
Muzaffarnagar, U. P.

A HINDU male, aged 24, came to me on 24th May, 1925, with a fistula in the perineum just at the root of the scrotum and gave the following history:—

"Since July 1924 I had been passing some discharge from the urethra and feeling burning sensation when passing urine. In November last I had an attack of fever and my urine stopped completely for two days. On the third day I had the present wound through which urine began to dribble and no urine came through the meatus. After two days I began to pass urine through the meatus drop by drop and through this wound as well. Since then my condition is the same."

On questioning whether he ever passed blood from the urethra or whether his stream ever stopped while micturating, he answered in the negative and said that he often passed pus and felt much burning just before passing the urine. (The patient is not an intelligent man at all.)

I thought it to be a case of perineal fistula after stricture of the urethra due to gonorrhoea and decided to scrape the indurated margins of the wound, dilate the urethra and keep a rubber catheter in.

After making necessary arrangements the patient was put under chloroform. I tried a No. 12 rubber catheter and to my surprise it passed into the bladder without any difficulty whatsoever. I then took out the catheter and passed a stone sound and felt a stone. I wanted to remove the stone through the perineal wound but the patient's father did not agree to this.

The indurated margins of the fistula were well scraped and a No. 12 rubber catheter was left in. Daily dressing went on for four days with rapid improvement in the wound. On the 5th day the patient came to me with the complaint that although the catheter was in he could not pass urine. I took the catheter out and found the stone lodged in the urethra about one inch above the meatus. I was able to take out the stone with great difficulty because of its hardness and size and had to slit the meatus. The perineal wound healed up within 10 days of operation and the case was discharged cured. The stone weighed 24 grains.

The interesting points in the case are :—

(1) The stone first descended into the urethra, blocked it completely, caused the fistula and then passed back again into the bladder.

(2) The stone was caught into the eye of the catheter, and the urethra which could not allow it to pass before was so dilated with the catheter that now the stone could pass through it.

(3) The patient being very unintelligent had refused any further operation for the stone ; his luck helped him and cured him.

AN ENLARGED WANDERING SPLEEN MISTAKEN FOR AN OVARIAN TUMOUR. SPLENECTOMY AND RECOVERY.

By J. N. SEN, M.B. (Cal.), M.R.C.S. (Eng.),
L.R.C.P. (Lond.),

*Deputy Chief Medical Officer, Tata Iron and
Steel Co., Jamshedpur.*

RASUN, a Mahomedan woman, aged 28, was admitted into Tata's hospital on 10th January, 1925, for a painful swelling in her abdomen, from which she had been suffering for the last two years.

About two years ago she noticed a lump on the left side of her abdomen which did not cause any pain and was unaccompanied by any fever. The lump gradually became bigger and painful until it attained its present size.

Present Condition.—The patient is thin, ill-nourished and anæmic. The lump occupies the whole of the lower abdomen from 2 in. above the umbilicus down to the pelvis, occupying more of the right side of the abdomen. An ill-defined margin could be felt in the left side of the lump but on the right side it was rounded and no such margin could be detected. Above, it was rounded, and below, it dipped down into the pelvis and its lower end could not be differentiated. The lump was painful and tender on pressure and a distinct thrill could be elicited over the lump. She preferred to lie on her right side as dorsal decubitus and the left lateral position caused her extreme pain.

Menstrual History.—Her menses had been regular and she had no children. She had an abortion a few years previously.

Examination *per vaginam* revealed an os of normal consistency but it was pushed forward. The lump could be felt through both the fornices but more through the right. Rectal examination revealed nothing except that the lump could be felt pressing over the anterior wall of the rectum.

Heart and Lungs.—Heart sounds were normal but were quick. Occasional râles audible on both sides of the chest, and breath sounds were slightly deficient at the base of the back of the right lung.

The liver was not enlarged and the spleen could not be felt.

The temperature on admission was 100.2°F. It ranged between 99°F. and 100°F. from the time of her admission, i.e., from 10th January, 1925, to 22nd January, 1925, after which it was either normal or subnormal.

Blood Count.—Unfortunately a detailed blood count which was made on 11th January, 1925, could not be traced but it revealed an anæmia of pernicious type, the colour index being above 1. No malarial parasites were found. The blood picture also showed megaloblasts, normoblasts and poikilocytosis. The history sheet says that no nucleated red cells could be found on 26th January, 1925.

Treatment.—She was put on increasing doses of arsenic and at the end of a month and a half she made good progress both as regards the anæmia and her general condition which improved considerably; the lump in the abdomen showed no difference in size but all pain from it was gone. The thrill which was easily obtained at first was not so marked now.

It was suggested to her that she should have the lump removed as it was thought to be an ovarian tumour. She agreed to this.

Operation.—On 2nd March, 1925, a median subumbilical incision was made under chloroform anæsthesia. The abdomen was opened and a dark-coloured swelling with numerous adhesions was found occupying the subumbilical and pelvic regions. The colour of the tumour was against ovarian tumour which is generally of a dark greeny-blue hue.

The adhesions both intestinal and omental were either wiped off or ligated and cut through. One of these latter adhesions consisted of two big omental vessels which were found implanted on the tumour. Of this more later on.

Dr. Chakravarti, Chief Medical Officer, who was present at the time suggested that the tumour might be the spleen. He was found to be right, as on tracing the tumour I found that it had a long pedicle emerging from under the left costal arch. The pedicle which did not impart any pulsation to the palpating fingers was clamped and cut through. The tumour could then be shelled out quite easily as the adhesions were dealt with

before. It was found to be an enlarged spleen with a long pedicle twisted on itself. The abdomen was closed in layers and the patient put back to bed. She made an uninterrupted recovery, though she gave me a few anxious hours after the operation. The spleen weighed 4 lbs. 12 ozs.

Remarks.—The patient's condition on admission and after examination of her blood was diagnosed as pernicious anæmia, though she improved under increasing doses of Fowler's solution it was thought to be only a remission of the disease which would again flare up probably to end fatally. As she improved considerably both in her blood picture and in her general condition it was thought to be the best opportunity for removal of the tumour which was tentatively diagnosed as ovarian tumour. On opening the abdomen the tumour was found to be an enlarged wandering spleen twisted on its long pedicle. The two big blood-vessels from the omentum implanted on the tumour, as mentioned before, were feeding the starving spleen. The thrill which was quite distinct at the time of admission and which became indistinct later on was probably due to sudden distension and over-filling with blood of the venous sinuses in the spleen due to sudden occlusion of the blood-vessels of the spleen brought on by the twisting of its lengthened pedicle. The constant pain over the tumour which she complained of at the time of admission was probably due to stretching of the capsule of the spleen due to sudden enlargement of the organ. The pain in the left lateral position was probably due to falling of the spleen on that side with consequent dragging of the adhesions. The woman was last seen about a month ago, i.e., 4 months after operation, quite healthy. She has gained in weight and is going about her ordinary work.

My thanks are due to Drs. P. N. Sen and S. N. Sen for compiling these notes for me and to Dr. J. C. Roy who did the blood examination.

A UNIQUE CASE OF MULTIPLE NEURO-FIBROMATA.

By Mrs. E. BERNARD CARR,

Senior Medical Officer, Women and Children's Hospital, Vannarpet, Tinnevely District.

THE patient, a woman, 40 years of age, from Srivaikuntam, in the Tinnevely District, was admitted on 13th May, 1925, with diffuse neuro-fibromatosis. She had numerous fibrous growths of the skin (spherical in shape) all over the body, varying in size from a pea to an olive, but what is of interest is that one of these growths on the right breast grew so rapidly that the breast became elephantoid in size and it was for this that she sought treatment.

She gave the history of having had these growths from early childhood, and that they grew in number and size as she grew older. She had three children, the last one was born 11 years

ago. It is only 2 years since that the breast began to hypertrophy.

The nipple was 10½ inches from the chest attachment. When not supported, the breast reached down to the knee.

The breast was amputated on 16th May, 1925, by Captain V. Mahadevan, District Medical Officer, Tinnevely, and the wound healed in 10 days.

The weight of the tumour after removal was 3½ lbs.

MULTIPLE SOFT FIBROMATA OF THE FACE.

By GANAPATI PANJA, M.B.,

Assistant Professor of Bacteriology, School of Tropical Medicine and Hygiene, Calcutta.

MAHAMMAD ISMAIL, Mahomedan male, aged 26, motor-driver, of light-black complexion and of excellent health, residing at 111, Baker's Lane, Calcutta, came for treatment for nodular lesions on his face which first started on his nose; duration 6 years; (*vide photo.*).

At first sight the disease looked like leprosy. There were nodules on the nose, eyebrows, chin and lobes of the ears, the nose being most affected and disfigured. Besides nodules there were also scars on the nose.

The nodules were soft, pinkish, and varied in size from a mustard seed to a pea; some were pedunculated and looked like papillomatous growths. The nodules on the nose joined with one another and gave rise to a diffuse corrugated swelling.

There were no subjective symptoms. The patient did not give any history of any family predisposition to the disease and denied syphilis and gonorrhoea.

On examination of a smear from a cut nodule no acid-fast bacilli were seen; mononuclear leucocytes and a few yeast-like organisms were found.

One nodule was cut aseptically and a culture was made on blood and ordinary agar slopes from the cut surface; only diphtheroid colonies were visible after 48 hours. A microscopic section of the nodule showed the following:—Papillæ flattened; a layer of loose cellular tissue present

beneath the epidermis; no signs of malignancy; corium mainly showing fibrous tissue with young fibroblasts; and no acid-fast bacilli seen.

Major G. Shanks, I.M.S., Professor of Pathology, Calcutta Medical College, also examined the sections and gave a diagnosis of soft fibroma.

About a week after another nodule was cut aseptically and a culture taken; again the diphtheroids were obtained, so an autogenous vaccine was prepared.

The patient had had 17 injections of salts of margosoic acid before he came to me and said that he had slightly improved, but that he did not wish to continue them as they had not been very efficacious.

I gave him Mist. pot. iodide, grs. 10 to 1 oz., for a week and then increasing the dose to grs. 15 asked him to continue another week, but found no appreciable improvement. Locally only ung. borovaseline was prescribed.

I then began injecting him with the autogenous vaccine, beginning with 10 mils. Ten injections have been given, the last one being 100 mils. The nodules have diminished in size but the improvement is not very satisfactory; the patient is highly satisfied and insists on the injections.

The disease is evidently a multiple soft fibroma of the face of unknown origin. It is not leprosy, although clinically it appears like leprosy. Can this be due to *B. diphtheriae*?

The patient is still undergoing treatment.

A SIMPLE CURE FOR LEUCODERMA.

By P. BHASKARA RAU, L.M.P.,

Medical Officer, Local Fund Hospital, Narasapatam, Vizagapatam District.

DURING April 1924, I developed a leucodermic patch on my chin, slightly to the right side. It started as a small white area about the size of a split pea and rapidly grew to the size of an eight anna piece. There was slight itching at the beginning. About 15 days later a second patch appeared on the ventral aspect of the left forearm, six inches above the wrist joint, and rapidly grew to the size of the patch on the chin. About a week afterwards I noticed a big patch on the whole of the inner aspect of the pinna of the left ear.

I showed it to many distinguished medical friends who all diagnosed it as leucoderma. I was advised to try Hormotone tablets (G. W. Carnick Co.) and various other tonics internally and tincture of iodine, tinct. ferri perchloride, all the mercurial ointments singly and in combination, iodised phenol,—in short everything that has even a faint action on parasites of the skin—externally. At this stage, i.e., after three months of unsuccessful trial of all the above medicines, as a last resource I showed it to my friend, Dr. C. Mallik, L.R.C.P. & S. (Edin.), L.F.P.S. (Glas.), of Vizagapatam, who kindly gave me the following Ayurvedic recipe:—

Yellow orpiment	..	1 part.
Seeds of <i>Psoralea corylifolia</i>	..	4 parts.

Both the above to be mixed and finely powdered. To the powder add a sufficient quantity of fresh cow's urine to make a thick paste and apply externally, frequently.

I was frankly sceptical about the result, but the cure was speedy and sure. In a fortnight all the three patches completely disappeared, and though it is nearly a year now since I used this treatment I have not noticed these patches again.

Both the drugs are to be had in every bazar in India. The seeds are called *Bavanchi ginjalu*, *Kralugechha vittulu*, *Karubogi vittulu*, and *Kala ginjalu* in Telugu and *bhavanchi*, *vakuchi*, *soma-rajee*, *Somavalli suvalli*, *avalunga*, *Krishna phala*, *Puti phala*, *Chandra-rekha*, *soma*, and lastly *kushtughna* (a very suggestive name) in Sanskrit.

Ayurvedic physicians recommend that the juice of the seeds be given internally for a lot of other diseases, but I have no experience about its action.

Before concluding I wish to add that any pure drinking water appears to be as useful as cow's urine, in the treatment of this condition. The total cost of the treatment is only half an anna.

[Note.—*Psoralia corylifolia* is better-known as *Bouchi* seed. It is well known as a "remedy" for leucoderma. It has been used in the treatment of this condition for some years at the School of Tropical Medicine, Calcutta. It has beneficial results in certain types of leucoderma.

We think with the writer that pure drinking water is probably as useful as cow's urine, even when the latter is available. Editor.—I.M.G.]

AN UNUSUAL CASE OF MALARIA.

By NISANATH GHOSH, M.D. (Cal.),

Civil Assistant Surgeon, Assam.

In 1922, while I was at Kohima, the following case of malaria came to my notice:—

S. L., Hindu male, aged 30, a 'Naik' of the Assam Rifles, was brought to hospital on 5th October, 1922, at midday in an unconscious condition. He had complained of headache and malaise that morning and dropped down unconscious about an hour before admission.

Condition on admission.—The patient was lying flat on his back, unconscious, and he did not respond either to a call or touch. His eyes were closed; pupils contracted, equal, and sluggishly responsive to light; conjunctivæ responsive to touch. Respiration was deep and stertorous at times, 16 per minute; pulse somewhat quick and soft, 88 per minute; temperature 97°F. There was nothing abnormal about his heart, lungs and bowels; the spleen and liver were not enlarged, and he was passing urine involuntarily at times. A catheter specimen of the urine showed no trace of albumin, sugar, diacetic acid, acetone or tube-casts. The odour of his breath and the condition of his eyes, ears, nostrils and mouth supplied no clue to the cause of his comatose condition. The knee-jerks were exaggerated; Babinski's sign absent, and Kernig's sign present.

The patient had four convulsive seizures on the left side of the body at irregular intervals.

Kohima was a very malarious (mostly M. T. infections) place at that time, so peripheral blood films of all febrile and doubtful cases were examined for malarial parasites. This was done in this case and about 2 to 4 malignant tertian rings were detected in almost every red blood corpuscle, so a diagnosis of malignant tertian malaria was made.

Treatment and Progress.—Quinine bihydrochlorid grs. viii in 10 c.c. intravenously, and $\frac{1}{2}$ c.c. pituitrin subcutaneously (to counteract the fall of blood pressure) were administered at 4 p.m. on the day of admission. Next morning the temperature rose to 103°F. but the patient regained consciousness and the convulsions ceased. Intravenous quinine in the same dose was continued for six days altogether. The temperature dropped to normal on the third day and recovery was uneventful.

From 11th October, 1922, quinine, grs. x.b.d., was given by mouth and on 14th October, 1922, when the parasites had disappeared from the peripheral blood the patient was discharged from hospital.

NOTEWORTHY POINTS.

1. Sudden onset with unconsciousness and convulsions.
2. Absence of fever and no enlargement of the spleen at the onset,—especially the former.
3. Rise of temperature but recovery of consciousness after first dose of intravenous quinine.
4. Presence of fever for one day only.
5. Presence of parasites in peripheral blood films even after 8 days' administration of quinine (including intravenous quinine for 6 days at grs. viii per day).

PNEUMONIA AND CELLULITIS TREATED WITH INTRAVENOUS IODINE.

By S. N. DATTA, L.M.P.,

Titabar Tea Co., Ltd., Titabar P. O., Assam.

I HAVE had the opportunity of treating some cases with intravenous injections of tincture of iodine and have had very satisfactory results.

The first was an adult female with the typical signs and symptoms of lobar pneumonia affecting both lungs. I applied anti-phlogistine to the chest, gave 1/30th gr. of strychnine sulphate hypodermically every two hours, an alkaline mixture with digitalis four hourly and 5 grs. of quinine sulphate in solution twice daily. The patient was put on a fluid diet and given brandy occasionally. In spite of eight days of this vigorous treatment I could detect no signs of improvement, so determined to give intravenous iodine a trial. So in addition I gave tincture of iodine in $\frac{1}{2}$ c.c. doses with 5 c.c. of distilled water on

alternate days intravenously. After two such injections the dose of iodine was gradually increased by 3 or 4 minims to 1 c.c., as also was the amount of diluting water until its maximum of 10 c.c. was reached. Immediately after each injection she had a slight rigor when she was given hot tea or milk to drink. The day after the third injection there was marked improvement and after the 5th or last injection an uneventful convalescence set in. She was discharged from hospital after about three weeks.

The second case was a coolie woman, aged about 30, who was admitted to hospital with severe spreading inflammation of the right leg with threatening gangrene and well marked pyrexia which resulted from a small perforating wound acquired while manuring tea bushes a few days before. I made several free incisions but despite these measures the patient's condition remained the same, in fact the ulcers formed by the incisions tended to slough. Then I put her on intravenous iodine as above and from the second injection the improvement was pronounced. After four or five injections she made a satisfactory recovery.

In four or five other septic cases I tried intravenous iodine with uniform success.

It would be interesting if other readers of this journal who have tried this simple remedy in similar cases were to record their findings.

NOTES ON CASES OF ACUTE YELLOW ATROPHY OF THE LIVER.

By Y. S. ROW, I.M.P.,
Alipuram Jail Hospital, Bellary.

Case 1.—The patient, a Moplah, aged 25 years, was admitted into hospital on 17th February, 1925, with a history of severe vomiting and jaundice. He was talking well at the time of admission. In the night at about 10 P.M., i.e., about 14 hours after admission, he became restless in bed and very irritable; tried to get up from bed and did not answer any questions. It was with the greatest difficulty that he was kept down in bed. His pulse was very slow, 58 per minute. As he did not pass urine after noon, it was drawn through a soft catheter. The urine was very dark coloured and contained bile; there was neither blood nor hæmoglobin. Next day there was slight rise of temperature to 100°F.; pulse became rapid. The liver dullness was greatly diminished. Leucin and tyrosin were present in the urine. The patient was still in the same unconscious state from which he did not recover. He died on 19th February, 1925.

A post-mortem examination was conducted and the following signs were noted:—

All the abdominal organs were deeply stained with bile. Small patches of hæmorrhage were present over the outer surface of the large intestine. The liver was very small, flabby and greenish-yellow in colour, and weighed 30 ozs. There were also small hæmorrhages in the substance of the liver. The organs of the thorax were normal except for being bile-stained. The meninges of the brain were highly congested and there were also minute hæmorrhages in the substance of the brain.

The case was diagnosed as acute yellow atrophy of the liver, by our medical officer, Dr. V. J. Lopez, I.M.D., and to confirm the diagnosis, a portion of the liver was sent to the Professor of Pathology, Madras, who confirmed the diagnosis.

Case 2.—The patient, a Moplah, aged 35 years, had been in previous good health. He gave a history of slight fever and jaundice since 1st April, 1925. His bowels were constipated. On 6th April, 1925 his temperature was 102.4°F.; pulse rapid and 120 per minute. He had severe vomiting. Convulsions soon set in on the same day. Later on he became unconscious, passing into a deep coma. The liver dullness was greatly diminished; urine was highly coloured and bile-stained. There was congestion of the bases of both lungs. The patient did not recover consciousness and died on 7th April, 1925.

Post-Mortem Signs.—All the internal organs were deeply bile-stained. Small hæmorrhagic patches were present over different parts of the small and large intestines. The liver was small, soft, flaccid and dark-yellow in colour with lighter yellow nodules in its substance and weighed 34 ozs. There was slight consolidation of the bases of both lungs.

The case was diagnosed as acute yellow atrophy of the liver, by our medical officer, and a section of the liver was sent to the Professor of Pathology, Madras, who confirmed the above diagnosis.

The above two cases occurred within a period of two months of each other. On referring to the old case sheets, I found another case which occurred in July 1923, which though diagnosed as acute toxic jaundice was most probably another case of the above disease. The notes are given below.

Case 3.—The patient, aged 25, was admitted into hospital on the evening of 17th July, 1923, with a temperature of 101.8°F. with a little abdominal pain, the latter of 4 days' duration. The bowels were constipated and there was tympanites present. The blood examination was negative to malaria. He developed severe jaundice the next day, became restless and unconscious, and the pulse was rapid. Urine was greenish-yellow; retention of urine was present. He did not recover from

the unconscious state and died on 18th July, 1923.

Post-Mortem Signs.—Both lungs were congested. The thymus gland was enlarged. The abdomen contained $1\frac{1}{2}$ pints of yellow bile-stained fluid. The liver weighed 26 ozs., was studded with small nodules of yellow colour, and on section was very tough. The intervening substance between the nodules had no appearance of a normal liver. There was slight congestion of the cæcum. A Meckel's diverticulum was present about 2 feet from the cæcum and presented neither congestion nor strangulation. The brain was highly congested.

Unfortunately the liver was not sent for pathological diagnosis. From the similarity of signs and symptoms of the last case with the above two cases, this might also have been another case of acute yellow atrophy of the liver.

These are the only three cases that occurred since the opening of this jail in October 1921, till the time of writing this note. There does not seem to be any special reason for the occurrence of the above disease which is a very rare one.

I am very grateful to our medical officer, Dr. V. J. Lopez, I.M.D., for his kind permission to publish the above notes.

THE UP-GOING TOE.

By CAPTAIN M. S. H. MODY, M.B., B.S. (Bom.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), D.T.M. & H. (Lond.),

Physician to the Out-patient Department,
Sassoon Hospital, Poona.

IN their most interesting and instructive contribution on "The Babinski or Extensor Form of Plantar Response in Toxic States, apart from Organic Disease of the Pyramidal Tract System," appearing in the *Lancet* of 10th January, 1925, Elliot and Walshe make an appeal to examine this question of an up-going toe in the various toxic comas. They word it ".....but the accumulation of evidence from one hospital is slow. This preliminary paper is therefore written in the hope that other physicians may be inclined to examine the question in the various toxic states that chance to come under their observation, and that so a body of information may be collected from which it will be possible to deduce the general principles that govern the form of the Babinski reflex".

My plea for these few lines is the following case:—

A young Mohamedan boy, 18 years of age, was brought to the out-patient department in a stuporose condition; there was extreme restlessness (suggesting toxic influence on the brain); pupils dilated and reacting to

light; severe jaundice; yellow discoloration of the conjunctivæ but not of the skin; temperature 101°F. ; pulse 95; liver not felt; spleen not enlarged; knee jerks++; ankle jerks++; ankle clonus+; and extensor response of the plantar reflex on both sides.

The history being that a fortnight ago he had an attack of jaundice ushered in by fever with rigors, the fever lasting for two days followed by vomiting, and the typhoidal state had set in only two days before he was brought to hospital. He died the same night, the temperature before death being 107°F. with a pulse rate of 148 and respirations of 60. Unfortunately a post-mortem was not performed, and in the absence of our knowledge of the liver condition, the surmise is that it may have been *cholæmia*, setting in as a fatal complication of catarrhal jaundice, or it may have been acute yellow atrophy of the liver.

In *cholæmia* there is liver destruction with a comatose condition from toxic influence on the brain, leading to extreme restlessness, coma, and a double extensor response.

SYPHILITIC DYSPNŒA SIMULATING AN ASTHMATIC FIT.

By M. G. RAMACHANDRA ROW, M.B., C.M.,

Chief Medical Officer, Town Hospital,
Pudukkottai, Trichinopoly.

A WELL-NOURISHED male, aged about 42, of good position, complained of cough and slight tickling sensation in the throat. On examination I found there was slight congestion of the throat and a few râles over the chest, here and there.

Two days later the irritating sensation in the throat increased and the cough got worse and he developed dyspnœa simulating an asthmatic attack. There was slight rise of temperature ranging between 99°F. and 100.4°F. and severe dyspnœa with typical cooing rhonchi and râles all over the chest.

Cardiac and renal asthma were eliminated after careful examination of the heart and urine, and the case was treated as one of bronchial asthma. The patient was put on the usual asthmatic mixture and in addition he had injections of adrenalin chloride solution, 10 minims on two occasions, and injections of morphia sulph. $\frac{1}{4}$ gr., atropine sulphate 1-150th gr. on 8 different occasions. Each injection gave him relief for about 4 to 5 hours, but the symptoms appeared again with doubled force.

After a week's treatment when I saw that there was no relief and the patient was getting worse, the idea that the patient was syphilitic struck me and I immediately started on anti-syphilitic treatment.

I injected sulfarsenol three times at intervals of 5 days, intramuscularly as he refused to take intravenous injections. After the third injection the dyspnoea disappeared like magic and the patient gradually picked up from that date. He is now perfectly all right. This case is sent for publication, as practitioners are likely to miss syphilis as a cause of dyspnoea and it should also be taken into account in all cases of asthmatic fit.

If this were a pure and simple case of bronchial asthma, one or two injections of adrenalin chloride and the usual stock mixture would have been likely to tide over the attack and give permanent relief, but in this case the dyspnoea lasted for fully 23 days, except for a few hours when he had either the adrenalin or the morphia and atropine injection.

A CASE OF MALARIAL PROSTATITIS WITH REFLEX RETENTION OF URINE.

By CAPTAIN S. L. CHOPRA, M.B., B.S.,
Dera Ismail Khan.

SEPOY YADAR, aged 20 years, strong and healthy, of the Frontier Constabulary, Daraban, was admitted into the Civil Hospital, Dera Ismail Khan on the 6th May, 1925, for retention of urine, fever and headache.

Family and previous histories were of no importance. He gave no history of gonorrhoea.

On 2nd May, 1925, he developed headache and fever at Darazinda post and next morning had retention of urine, which was relieved by a warm sitz bath. He had retention again in the evening and was evacuated to Daraban, where he remained for three days, during which time he was relieved by catheterisation. Fever and headache continued, the temperature being remittent. He was evacuated to Dera Ismail Khan.

On examination he had a palpable spleen, furred tongue and a full bladder, containing sixteen ounces of urine (removed by catheter) which was normal. On rectal examination the prostate was slightly but distinctly enlarged and extremely tender. He had severe headache and temperature 100°F. No mechanical or nervous cause to explain the retention of urine could be traced nor were there shreds in his urine by the two-glass test. The blood was examined and he had a heavy infection of sub-tertian malarial rings. He was put on acid-cinchona mixture with arsenic; the next morning the fever and headache had both vanished. Patient passed urine himself and rectal examination on 8th May, 1925, revealed that the enlargement and tenderness of the prostate had altogether disappeared. He was kept on cinchona and graduated doses of arsenic and had no recurrence of the trouble. He left hospital cured on 25th May, 1925.

This case would strongly suggest that the malignant tertian parasite, which is well known to possess the property of accumulating in the cerebral and intestinal vessels, can do so—as would seem in this case in the prostate, and is a striking illustration of the wisdom of the instruction:—"Examine the blood in all cases of fever".

I am indebted to Major J. B. Hance, F.R.C.S.E., I.M.S., Civil Surgeon, Dera Ismail Khan, for permission to publish the case.

A CASE OF RESUSCITATION AFTER CESSATION OF THE VITAL FUNCTIONS FOR OVER 15 MINUTES.

By N. C. KAPUR, B.A., L.R.C.P. (Lond.), M.R.C.S. (Eng.)

MAJOR, I.M.S.,

Resident Physician, Medical College Hospital, Calcutta.

A HINDU male, R. C., aged 80 years, was brought to the Medical College Hospital at 10 P.M. on the 13th of July, 1925, suffering from severe dyspnoea—the result of laryngeal obstruction due to a malignant growth of the larynx. As his case was urgent, he was taken straight to the operating theatre for the performance of tracheotomy. When the patient was placed on the table, he suddenly stopped breathing. On examination, the heart sounds were found absent, the pupils were dilated and the eyes were fixed. Artificial respiration was immediately started and tracheotomy was performed when the patient was apparently dead. The patient's chest was continuously flicked with a cold wet towel. For fully 15 minutes there was no response. There was complete cessation of breathing, heart sounds were absent, there was no pulse at the wrist, and the patient's face had the usual cadaveric characters. Just when all hope seemed to have been lost, the patient's chest was flicked in a forcible manner and, to the surprise of everybody present, the patient took a shallow breath. The flicking was continued and after a minute the patient took another breath. The pulse was now perceptible at the wrist and the heart sounds could just be heard. The respiration gradually established itself. The patient has been doing well since except that he is suffering from a malignant growth.

I am publishing this case as, although I have had several cases of laryngeal diphtheria where there has been a complete cessation of breathing and heart's action for 5 to 7 minutes and the patients have been resuscitated, I have not had a case of inspiratory dyspnoea where a patient has been revived after a complete cessation of vital functions for over 15 minutes.

The case is published by the kind permission of Lieutenant-Colonel F. P. Connor, D.S.O., F.R.C.S. (Eng.), I.M.S. My thanks are also due to Assistant Surgeon Provash Chandra Banerji, the Officer on Duty, Medical College Hospital, who helped me in the operation, and who patiently and

continuously carried out the most tiring duties of artificial respiration for more than half an hour.

A CASE OF BULLET WOUND OF THE CHEST FOLLOWED BY PLEURISY WITH EFFUSION.

By RAM LABHAYA, L.M.S.,

Assistant Surgeon, Civil Hospital, Pind Dadan Khan.

MUSSAMAT KARAM BHARI, aged 35, of the village Wabula, was shot by a pistol on the night of 19th June, 1925. She was brought to the Civil Hospital, Pind Dadan Khan by the police on 20th June, 1925, for examination and treatment. There was a bullet wound $\frac{3}{4}$ in. by $\frac{1}{4}$ in. going through the chest wall on the right side of the chest, $2\frac{1}{2}$ in. below and to the inner side of the right nipple. Blood was coming out of the wound. There was no exit wound, but on the back in the middle line a hard mass feeling like a bullet was felt under the skin, a little higher in level than the wound in front. Her pulse was 94 per minute, respiration 56 p.m., and temperature 100.4°F .

Her condition began to improve in hospital and on 29th June, 1925, when the wound in the chest had nearly healed, after incision on the back the bullet was removed and the wound stitched. One end of the bullet was bent, which might have been due to its striking against the vertebrae.

By 7th July, 1925, the wound on the back had healed but she was getting slight fever— 100° to 101°F .—and the respiration was hurried. Dulness on percussion and fulness of the interspaces on the right side of the chest developed, so the chest was aspirated on 16th July, 1925, and 26 ozs. of bloody fluid was withdrawn.

There was some improvement, but fluid filled in again so she was again aspirated on 27th July, 1925, and 32 ozs. of bloody fluid was again withdrawn. After this her temperature and respiration rate came to normal and she was discharged cured on 18th August, 1925.

The case is of interest because after a bullet wound which had gone right through the chest the woman recovered. Throughout her illness there was no cough, which meant that the lung had not been injured.

AN INTERESTING CASE OF TRANSVERSE PRESENTATION.

By MADAN H. JHAVERI, M.B., B.S. (Bom.),
*Medical Officer, Loinwe, Kengtung Subdivision,
Southern Shan States.*

The patient was a primipara, 16 years of age, of short stature and quite healthy. She was seen and examined by the Sub-Assistant Surgeon, Kengtung, on 8th June, 1925, who found the foetus was in the normal second position—9 months and 7 days old (according to the patient). The pelvis was slightly contracted.

On 14th June, 1925, she was brought to the hospital at about 11 p.m. When examined by the Sub-Assistant Surgeon he found that the foetus had turned its position, i.e., now the foetus

was in the first transverse position. He could only elicit from the patient that the pains had begun during the day and the uterus was massaged from time to time by the patient and her friends. When she was admitted the pains were irregular. He tried his best to correct the position by both versions but he could not succeed. He sent for me in the middle of the night. I reached Kengtung in two hours and a half—a distance of 17 miles. When I examined the patient the foetus was in the first transverse position and the uterus was regularly and continuously contracting. The only course left open was to extract the foetus in the breech position. The patient was put under chloroform; the cervix was fully dilated. The hand was passed under the foetus and the nearest leg, that is the right, was searched for. Both the legs had become extended but they were brought out safely. The hands were then brought out. The after-coming head gave difficulty owing to the contracted pelvis but it was brought out safely by Smyly's method. The placenta came out without any trouble. The child when weighed was $8\frac{1}{2}$ lbs. and was well developed.

The patient was febrile, the highest temperature being 101°F . on the sixth day, although all aseptic precautions were taken. She was given the usual quinine and ergot mixture and hot vaginal douches, and for three days tinct. iodine (5 minims) was injected intravenously. The patient is doing well and at the time of writing the temperature was normal.

The question arises as to whether it is possible that after the foetus was in normal position at full term, the position could be changed even after undue manipulation by the patient. Up to the present I have managed six cases of transverse presentations at Bombay and at Bassein, but in no case was the foetus at full term.

INTRA-MUSCULAR INJECTION OF UREA STIBAMINE.

By S. KUNDU,

Assistant Surgeon on Kala-azar duty, Sylhet.

Just after returning from Shillong and taking charge of my present duties in Sylhet. I was repeatedly asked by my Sub-Assistant Surgeons who are treating kala-azar cases whether urea stibamine can also be safely used intramuscularly, especially in children when the veins are too fine to be easily punctured. In order to satisfy their curiosity in this point, I should like to publish the following note which may help them in some way in undertaking the intramuscular use of urea stibamine.

In six of my cases where a little solution had escaped into the subcutaneous tissues at the time of intravenous injection, three had much pain in the site, swelling and induration and three had actually abscesses requiring opening. In two cases where deep intramuscular injections were given in gluteal region only pain was complained of for 2 days but no induration at all.

In spite of this experience in the intramuscular use of urea stibamine, I had occasion to treat a case, in a child of our own family, which requires publication as of some interest to the medical profession. This is the only solitary case, in our family, who lived in Barisal town since his birth and none had any occasion to mix with the kala-azar cases anywhere except myself, as my duty keeps me constantly exposed to kala-azar infection. The child had no occasion to live with me in Assam before he was actually sick.

The child, aged $1\frac{1}{2}$ years, was found to be suffering from suspected fever for 6 months and was taken to me for treatment through my advice. Past history shows continued type of fever for $1\frac{1}{2}$ months in the beginning and later irregular fever. Present condition gives—spleen up to umbilicus, liver 2 fingers below costal margin, anæmia and œdema most marked; leucocytes counting below 2,000, dysentery severe and temperature running 103 to 104. Diagnosis of kala-azar was made by finding Leishman-Donovan bodies in the peripheral blood and positive aldehyde test. Urea stibamine was started by intramuscular injection, veins being too thin for the needle. Ten injections were given in the doses of—

.01 gm.	in 1	c.c. of distilled water
.02	do.	do.
.04	in $1\frac{1}{2}$	c.c. do.
.06	do.	do.
.06	do.	do.
.06	do.	do.
.08	in 2	c.c. do.
.08	do.	do.
.08	do.	do.

every third day, representing a total of 0.65 gm. of urea stibamine and nothing was complained of except on the last injection. With these injections the patient was progressing well, temperature became normal on the fifth injection, spleen diminished, œdema completely disappeared, general constitution wonderfully changed and weight much gained. Intramuscular injections were given two in deltoid, six in gluteal, and two in thigh muscle and the result was very satisfactory on the whole, but on the tenth injection the child got very high temperature which continued for 3 days accompanied by much pain and swelling at the site of the last injection which was in the thigh. Intramuscular injection was stopped and, with the stoppage of fever, his general condition gradually improved and after a fortnight he appeared to be cured. Veins being prominent at this stage, 4 more intravenous injections (not intramuscular) in the doses of .05, .08, .1 gm. in 2 per cent. solution were given without any trouble with a view to prevent relapse, as spleen puncture could not be taken to know the sterility. The child is now quite healthy. It is a year since the child was treated by urea stibamine.

From this it appears that urea stibamine is not a very irritant drug like antimony tartrate, though

a little local irritation may be noticed in some when used intramuscularly or subcutaneously. In any case intravenous injection is the most suitable and popular method as this does not cause any irritation or pain at the site of injection, if given properly, but if intramuscular use is to be made, a great deal of precaution about the sterilisation of skin, syringe and solution is absolutely necessary. Any defect in these is sufficient to cause irritation in the site when used intramuscularly.

A CASE OF PERNICIOUS MALARIA TREATED WITH QUININE INTRAVENOUSLY.

By KHAGENDRA NATH CHATTERJI, M.B.,
Chinsurah.

ON 1st September, 1925, I was called in to see a young boy who became collapsed after violent vomiting and purging which followed an attack of fever. It was the fifth day of the attack, the fever used to come every day with shivering and was followed by diarrhœa and vomiting. On the third day the boy passed hæmorrhagic stools and became pulseless. His pulse was however restored by the injection of pituitrin by a local doctor, and the hæmorrhage from the bowels also stopped, but on the fifth day, the collapse was severe; the extremities, especially the upper, were cold and shrivelled, both pulses were almost imperceptible, the temperature was subnormal, there was agonising pain near the umbilicus and liver area accompanied with persistent bilious vomiting and purging. The stools resembled very much those of dysentery. The patient was restless and sighing in respiration. I took the history, and was told, that shortly after the boy had come back from Jessore, where he stayed a week, he had intermittent fever, which was usually followed by diarrhœa and vomiting. From the above symptoms and the history, I thought it might be a case of a bad type of pernicious malaria and this was confirmed when I found the spleen was much enlarged. I thereupon decided to adopt a method of treatment which would bring about the most prompt and sure effect, and I gave the patient quinine bihydrochloride 5 grs. intravenously, diluted with 20 c.c. of normal saline, with 10 minims of adrenalin chloride sol. added to it. This brought immediate relief with cessation of all the symptoms. The patient becoming quiet, I left him with instructions for a rectal saline to be given. When I left, I saw the patient was getting a reactionary rigor which was not severe. In the evening when I went to visit the patient again, I found him much better; his pulse had returned, his extremities were warm, and there was no more purging nor vomiting. The next morning I gave the patient quinine 5 grs. intravenously diluted with 10 c.c. of normal saline, and another on the following day. The boy is keeping well since then.

Indian Medical Gazette.

DECEMBER.

THE ANCIENT SYSTEMS OF MEDICINE.

MORE than three years ago the Government of Bengal appointed two Committees to report what steps could be taken for the restoration of the Ayurvedic and Tibbi systems of treatment, with special reference to the question of teaching these systems.

It is understood that these Committees have made their report to Government, but a recent resolution on the report of the Tibbi Committee indicates that the Bengal Government is conscious of the difficulties and drawbacks which would attend any attempt to maintain side by side, several rival systems of medicine. Many educated Indians believe that it is desirable to revive the ancient systems of medicine, and in some provinces action has already been taken to give practical effect to this view. It is necessary for practitioners of scientific medicine to study the question and to instruct public opinion on the results which would be likely to follow from the official recognition of a number of systems of medical practice.

To begin with, we must have clear ideas of the question of systems in general. In former times medicine was mixed up with religion and just as there were religious dogmas so there were medical or medico-religious dogmas which were based on the undisputed authority of accepted teachers. Even when the close connection between medicine and religion was broken in Western countries there were still systems based on certain preconceived ideas and war was waged between homœopathy and allopathy. Homœopathy taught that small doses of drugs were effective remedies for diseases in which the symptoms were similar to those caused by large doses of the drugs in question. Allopathy taught that when a certain symptom occurred in a disease the best treatment consisted in giving large doses of a drug which produced the opposite symptoms. It cannot be too widely known that modern scientific medicine does not accept either of these views, but concerns itself with the discovery of the causes of disease, with the removal of these causes and with the discovery of the best available remedies for the diseases. Allopathy is dead, and it is merely because the allopathists took most kindly to scientific methods and discarded their allegiance to preconceived notions that the name of allopath is still wrongly applied to the medical scientist.

Medical men who believe in science should indignantly repudiate the designation of "allo-

paths," they should make it clear that they stand for knowledge from whatever source it is derived. Homœopaths are now following in the same direction and need only drop the old name and the adhesion to the exploded basis of homœopathy to become eligible for admission into the brotherhood of medical science. Homœopaths rendered a considerable service to humanity in the past, the infinitesimal doses of medicines which were employed by them gave a chance to the great healing power of nature, at a time when the allopaths were poisoning their patients by large doses of harmful drugs. We must admit that some of the practitioners of our own times have not yet completely freed themselves from the evils of the system of allopathy. We cannot at once undo the harm that is caused by wrong traditions, but all who believe in science will press forward towards the truth, and we can safely claim that the spirit of modern scientific medicine is a humble search for more knowledge. We recognise the existence of only one true system of medicine, scientific medicine—based on observation and experience. Having looked to our own foundations and satisfied ourselves that they are sound, we must try to educate the public and get rid of the mistaken idea that we form one of several warring systems which are appealing for popular support.

We must also make it quite clear that we are prepared to look for and receive help from every source. We do not admit that there are Ayurvedic or Unani drugs which we refuse to adopt merely because they have not been generally used in modern medicine. Never has there been so ardent a search for better remedies, and if we can find a drug which is better than the one which we now employ, we insist on the right to use it from whatever source it may come. Suppose, for example, that practitioners of one of the indigenous systems were in the habit of using a drug which has a definitely curative action in diabetes, it would at once command a huge sale at enormous prices and when we hear of some obscure and struggling quack who says that he knows of such a drug his position is like that of a poor man who has a secret method of converting brass into gold and yet is living in abject poverty. From time to time we do hear of these wonderful remedies, and more or less hopefully put them to the test, but only to be disappointed by finding that they are useless.

Compare the advances which have been made by scientists in the discovery of new and potent remedies like the salvarsan group with those which have resulted from rummaging among the heaps of vaunted ancient drugs. It is not really surprising that the old drugs should yield such poor results; our present supply of remedies consists chiefly of substances which have been found by centuries of empirical use to have a certain value, and the reason why so many have been discarded is that they have not stood the test of observation and experience. In spite of this we

still continue the search, and we still hope that some drugs may have been discarded undeservedly, but we cannot be blamed if we press forward most especially with investigations of a type that has in the past yielded the more fruitful results. Medical scientists deny that they have their hands tied by any prejudices against remedies merely because they are not orthodox, they deny that there is any really useful form of knowledge which they refuse to adopt.

What then is the reason for the attempt to revive the ancient systems? Let us look at some of the reasons which have been brought forward by the advocates of such a course. It is claimed that scientific medicine has failed to meet the needs of the masses in India and that a cheaper system which uses less costly drugs will succeed where science has failed. But there is no evidence that science has failed, though the application of science may have been defective. Quinine has failed to make any serious impression on the malaria of India, this is not surprising when we consider the quantity of quinine that is available in our dispensaries, it is ludicrous to expect that three or four grains of quinine will produce any impression on a person suffering from malaria. The alternative is to employ some cheap drug which can be used freely, but when we come to ask which drug should be used, we find that there is not a particle of evidence that any cheap indigenous drug has the slightest effect on the malaria parasite. Much the same thing applies to all the remedies which have been proved to be curative in the other great diseases of India, and no government would dare to offer the people inert drugs, even if they cost nothing at all.

We might just as well offer the people straw and dust as articles of diet in times of scarcity, as offer them useless medicines when they suffer from malaria and dysentery. If cheap remedies are available to the practitioners of the ancient systems it is our business to find them out and to take them into use. To institute a farcical system of distribution of useless remedies would make any government which adopted it the laughing stock of the world. If cheap and potent drugs exist they are capable of being used by our existing practitioners whose training will enable them to judge of the efficacy of such drugs.

Another suggestion is that our modern methods of standardising drugs makes them too expensive, and therefore we are advised to resort to ancient methods of preparation. Can any one with scientific training countenance such a procedure? In the case of harmless and simple remedies standardisation is hardly needed, but then such drugs are of little value in the treatment of diseases which kill and maim.

Then it is argued that our courses of medical education are too costly, and the suggestion is that followers of the ancient systems can be trained on far cheaper lines for supplying medical relief to the masses.

If such practitioners are entrusted only with the harmless drugs, they need no training at all, but when it is a question of employing potent remedies we cannot readily adopt the suggestion of entrusting these to persons who are ignorant of their properties or of the methods of diagnosis of the diseases for which they are employed.

Efficiency in the diagnosis of disease and in the use of the remedies is absolutely essential, if we admit of a sacrifice of efficiency the sooner we cease to offer medical relief to the people the better. We do not find an outcry because our doctors are too efficient, quite the reverse, and those who have most closely studied the question maintain that our policy must be directed towards increasing efficiency and the employment of more scientific methods rather than towards a relapse to barbarism.

The railway train is horribly expensive, the bullock cart is cheap and simple, but we do not hear of any demand for the construction by Government of bullock carts instead of costly steam engines. The truth is that expensive and scientific appliances, in the long run, are by far the cheapest and therefore they have supplanted the old and wasteful methods of pre-scientific days. There is still a need for bullock carts in spite of the network of railways, but there is no need for a state organisation for the supply of these simple needs. In the same way there will for generations be a need and a demand for simple domestic remedies, but this need can easily be supplied by the people themselves; Government can only be expected to step in to provide the more expensive requirements which need a highly specialised organisation for their application.

Another point is that there are thousands of practitioners of the indigenous systems who could be made far more efficient if only they received a special training in modern scientific methods. But we have no evidence that they will accept this training, they certainly have made no demand for it and they are not likely to do so. The indigenous systems claim that they are perfect and complete, if their followers were to sit at the feet of scientific teachers this claim would have to be withdrawn and it is hard to imagine that the Ayurvedic or Unani practitioners would be so lacking in astuteness as to admit their inferiority in any respect.

It is an alluring prospect to imagine the indigenous practitioners being weaned away from the error of their ways by contact with scientists, but an insuperable obstacle lies in their over-weening confidence in their own superiority. Some of them, it is true, are painfully aware that the public is finding out the weakness of their claims, and they have a secret desire to learn some of the methods which are bringing such credit to medical scientists, but it is impossible to conceive of any cheap course of instruction which would

render the indigenous practitioners capable of handling the two-edged swords which medical men have learned to wield by years of patient study.

If we are to have a cheaper and more humble class of practitioners let us train them from the beginning, rather than attempt to eradicate the firmly rooted preconceived ideas of the followers of the systems. There are plenty of young men of intelligence and education who are only too willing to take up the medical career, the only difficulty lies in deciding whether it is possible or wise to adopt a shorter and cheaper course of training for medical men.

Another argument with which we are faced is that the ancient systems are natural to India and popular, and that the people are prejudiced against scientific medicine. The best reply to this argument is to visit one of the kala-azar dispensaries where we see the people crowding eagerly to receive intravenous injections. We hear far too much of the rooted prejudices of the Indian peasant; the truth is that when he has seen the value of any new method, whether in agriculture or medicine, he seizes on it just as eagerly as the most advanced European.

It is not so long ago since no orthodox Hindu would touch a dead body, yet our medical colleges and schools now have ten applicants for every available seat in their class rooms.

The advocates of the restoration of the ancient systems admit that the present practice of these systems has become debased, but they think that by search among the ancient writings the methods of their balmy days can be discovered and their ancient glories restored. Even if we were to admit that in the good old days the Ayurvedic system was complete and had perfect systems of surgery, midwifery and hygiene, this admission would not alter the present state of affairs, it would make us willing to take up the study of the old books and if a claim were made for funds for this purpose nobody would object. We might feel doubtful as to the ultimate value of the work, but when Universities spend large sums of money on pure and unproductive learning there can be no possible objection to their taking up so interesting a study as that of the ancient medical systems of India. It is strange that such bodies as the Calcutta University have not already done more in this direction. The systems as we know them at the present day are rich in claims, but more than claims are needed.

It would be just as reasonable to institute schools of training in alchemy and astrology with a tincture of chemistry and astronomy as to establish mongrel schools in which the ancient systems would be taught side by side with scientific medicine.

In either case the civilised world would first of all be astounded, but soon it would be dissolved in laughter at so incongruous a spectacle. India is rightly pressing her claims for admission

to the commonwealth of advanced and civilised peoples, her claims will not be advanced by a deliberate return to obsolete systems. It is even urged that properly trained practitioners of the ancient systems should be registered and recognised equally with western practitioners. Once this claim is admitted there must be equality of treatment, so that at each head-quarters station there will be an Ayurvedic Civil Surgeon, a Tibbi Civil Surgeon and a Homœopath each provided with a suitable hospital and dispensary. For a poor country a four-fold establishment of this kind will be a severe tax and the situation will be ludicrous: better far to decide which system is to be employed and refuse state aid to the others. We have not yet heard of any serious demand for the abolition of the existing medical officers, but if the state recognition of the ancient systems is carried to its logical conclusion this will have to be the next step, as we cannot afford to employ equal numbers of practitioners of all the systems in every place. The Madras Committee on the Ayurvedic system expressed the view "that there can be but really one system of medicine of which the existing systems are but parts" and "we would like to see the future practitioners in India, no matter what denomination they belong to, being so trained as to bring to the problem of ill health, not only the expert knowledge of their own system, but as far as practicable, the best that is in the other systems also."

This view really expresses the aim of scientific medicine which is striving to attain to perfection of knowledge, from whatever source it may be attained, but scientific medicine admits that it has still a long way to travel, while the other systems claim that they have already reached the goal. Nobody is so unteachable as the person who believes himself to know everything, and unless the practitioners of the systems "become as children" like the followers of science there can be little hope of their adopting this excellent ideal.

Should the practitioners of the systems become converted to this view, they would have to set their faces in the same direction as the scientific practitioners, and they would quickly find that they were travelling on the same road. As matters stand they are not likely to adopt this course, they would be compelled to give up their cherished belief in their own superiority and perfection, they would have to discard the comforting doctrine of self-sufficiency and would be compelled to gird up their loins for a long and toilsome journey.

It is not that we refuse to lend a helping hand to our brothers who belong to the ancient systems, far from it, but can those who admit their imperfection offer to teach those who claim to be perfect? Under the circumstances we prefer to live and we are sure that we shall best be able to maintain the amicable relations which exist

between ourselves and the practitioners of the indigenous systems if we follow our own path and allow them to do the same. If there be any widespread demand for the restoration of the ancient systems the first step must be made by the adherents of the systems, they must produce evidence that they can supply a public need which cannot be supplied by the existing scheme, but they are in the dilemma of knowing that if they can demonstrate the superiority of any of their methods as compared with the methods of scientific medicine, we shall, without hesitation, adopt the improvement which they have brought to our notice. To do so is in the interests of humanity and is perfectly fair; we have published every detail of our knowledge to the world, so is it not only right that the treasures of the ancient systems should also be published for the use of humanity?

It may be suggested that we are prejudiced, our interests are at stake so that we cannot be accepted as reliable witnesses in this matter. If this argument is raised we must appeal to the opinion of the whole civilised world, this has already been expressed in favour of scientific medicine, so that if we ask for a verdict from educated humanity they would be faced by the hard fact that it is a case of the whole world against the systems. European practitioners have discarded their own ancient system in spite of centuries of hallowed tradition, they cannot be accused of blind prejudice when they equally discard the systems which have been given up by the whole mass of educated opinion in India.

Let the practitioners of the systems place their cards on the table as we have done, let them admit that existing knowledge is far from perfect and that science has yielded up secrets of the greatest importance, let them join us in the search for truth and knowledge, and in the application of that knowledge and we shall receive them with open arms. Under existing conditions fellowship with them in medical practice is inconceivable.

It is surprising to find that the advocates of the restoration of the systems include a small number of intelligent Indian medical men who profess the firmest belief in modern medicine. It is hard to believe that they can be actuated by any motives other than expediency. There has been a good deal of loose thinking on the subject of the indigenous systems; it is time that we came down to hard facts.

To them we would like to put two questions: "Do you believe that there are drugs or methods of treatment, used exclusively by the practitioners of the ancient systems, which are superior to those used in modern scientific medicine?"

We should expect their reply to be in the affirmative; their attitude would otherwise be inexplicable. Our second question would be: "Can you suggest any reason why those superior drugs or methods should not be adopted by practitioners of modern scientific medicine?"

J. W. D. M.

SPECIAL ARTICLE.

A CRITICAL REVIEW OF DR. C. A. BENTLEY'S "MALARIA AND IRRIGATION IN BENGAL."

By C. STRICKLAND, M.A., B.Ch.,

Professor of Medical Entomology, School of Tropical Medicine and Hygiene, Calcutta.

THE purport of Dr. Bentley's work is the submission to Government of his opinion as to the causes of the malaria which afflicts the province of Bengal and to suggest a scheme for the amelioration of its condition.

The distinction of the author, the high place which he holds in the administration of Government and the magnitude of the issue, will ensure that what he says will receive most careful attention, and there is therefore no reason to apologise for the scrutiny of the paper which is here made in the hope that it may be helpful to those who wish to come to a right decision in the matter. All the more so as one of the theses submitted by the author is, as will be seen later, the basis of statements by laymen and politicians which have been used publicly as a rod wherewithal to beat the "Satanic Government."

Now that being the purport of the work, the title would suggest that the author has found the decline of agriculture to be the exciting cause of the trouble, but as one reads through the pages one finds that such has not been the case. The following passages show it, ".....the great increase of malaria disease..... is inextricably bound up with a coincident decline of agriculture owing to.....and....." (*vide* p. 65).

"The common origin of these associated evils is to be sought in....." (*ibid*). "The evidence incriminatingas the cause of both agricultural decline and increase of malaria is so overwhelming that....." (p. 67). "A greatly increased prevalence of the disease almost invariably accompanies the decay of agriculture" (p. 1) "..... has caused serious damage alike to agriculture and the health of the people." These and many other statements of a like nature indicate that the author had no intention of incriminating the condition of agriculture with the incidence of malaria, but that both conditions are the result of some other factor. That being so, such references to agriculture, which take up a large proportion of the work, appear to be irrelevant to the discussion and to have no more justification or value than would have a coincident analysis of the growth of anarchical societies in the community or of any other consequences springing from the same root.

Now the author in analysing his data predicates that deltaic tracts are not prone to malaria, e.g., those of the Nile, the Mekong, the great rivers of China and many others. Some however are so, as the Mississippi and the Gangetic plain. Why should some be malariagenic and not others? One possible reason is not mentioned by the author, viz., that one locality may support a mosquito fauna different from another. *Anopheles ludlowi* for instance is found in Malayan deltas but not in Indo-China. Such an instance shews that deductions made concerning one country are absolutely of no value in another.

It is the ubiquitous embankment of the Bengal delta that Dr. Bentley blames for the woeful condition of the province to-day. He would premise that any locality which has not been embanked, if any such exist, is perfectly healthy because it is subject to the normal flood and flush of river inundations and it is only the works of man that have

* "Malaria and Agriculture in Bengal. How to reduce Malaria in Bengal by Irrigation." By Charles A. Bentley. Director of Public Health, Bengal. Calcutta: Bengal Secretariat Book Depot, 1925. Price, Indian Rs. 2-2; English 4s.

Note.—The italics all through this paper are the reviewer's.

made it unhealthy. Thus, "there has been a great extension of malaria.....since the construction of several hundred miles of railway." "The indiscriminate embanking of vast tracts primarily for flood prevention and for the construction of the network of railways and roads that now covers the country, has caused serious damage.....to the health of the people." Then (p. 21 *et seq.*) he gives correlated statistics of the malaria and the mileage of embankments in the four great divisions of the province to support his hypothesis. He also cites (p. 34 *et seq.*) several instances where the construction of embankments for public works has been accompanied by epidemics; and another piece of evidence, culled from Stewart and Proctor, is that certain *thanas* in Murshidabad District outside the protection of an embankment have a lower spleen index than others inside it.

More generally, the author says that the deltaic area is potentially malarious *if the rivers are disorganised by human interference*, which usually lies in the form of works for improved communications or zemindary* bunding; and that there is reason to believe that many of the changes in the Bengal rivers during the last sixty years have followed the embankment of the country. He is clearly of the opinion then that embankments are the exciting cause of the trouble.

Dr. Bentley explains why embankments should have led to an increase of malaria. They have prevented the normal flood and flush of the land; no silt-bearing water has deposited its burden to level up the inequalities of the surface which are so favourable to mosquito-breeding, and the reduction of lineage of dangerous "edge" in the breeding places has not ensued. Further, he says, river inundation water seems *per se* to be inimical to anophelines, while rain-water is favourable.

Now, in reading the author's evidence in favour of his hypothesis, one is struck by one very salient fact. Although Eastern Bengal may not be so well provided with roads and railways as the other divisions, yet it has 163 miles per 1,000 square miles of area; moreover what it lacks compared to the other divisions in roads and railways probably owing to the land lying lower and more subject to inundation, it makes up with a greater number of zemindary bunds. Yet in spite of this degree of embankment the health is notoriously good. Dr. Bentley himself refers to it in these sentences "the delta tracts at present largely exempt from the disease," and "the future welfare of the country depends on its continued good health."

Then again, although Northern and Western Bengal have about the same mileage of rail and road embankments (about 300 per 1,000 sq. miles) yet Northern Bengal is very much more healthy, its increase of population in 1901-1911 being as 8.0 per cent. to 2.8 per cent. in Western Bengal.

If one then turns to the data afforded by the separate districts in any one Division there is the very important fact noted by Fry that Howrah District and the southern part of Hooghly District are strikingly non-malarious as compared with the adjoining Burdwan District, yet those districts are perhaps more embanked than any in the province.

Finally, if one turns† with the author to other countries and Lower Egypt be compared with the Presidency Division of Bengal, both are of about the same area; Lower Egypt has 3,600 miles of embanked roads and rails, and is, practically speaking, non-malarious, while the Presidency Division with about 4,000 of embanked works is very malarious.

It is justifiable then to conclude that notwithstanding the evidence cited to the contrary embankments *per se* are not dangerous, or at any rate not to any "economic" extent. Indeed, Dr. Bentley himself in one passage says that that is so, that they are only dangerous when the embanked land is not irrigated, and that irrigation schemes should always

include the embanking of rivers and improved means of communication. In this one sentence the author himself refutes the unqualified assertions of paragraph after paragraph and chapter after chapter.

Now if embanking the delta is not to be blamed for the state of affairs, can any alternative hypothesis be submitted? The reviewer reiterates that if there were not an embankment in Bengal except such as be naturally thrown up by the rivers the distribution of malaria would be precisely as it now is; and that the explanation lies in the existence of local variations in the natural physiography of the delta. One need not go into any detail concerning the structure of a delta—which has been fascinatingly portrayed by Ferguson (1912)—suffice it that the varying elements in the picture can be considered to be responsible for all that has been observed in the local incidence of the disease. Thus the great ill health of the Western Districts as compared to the Eastern may be due to the fact that the Western side of the delta has been raised and the rivers, having thus done their duty, have migrated to the East, leaving the "decayed" channels behind; these provide no flood or flush and that has brought malaria. Whether the land has been embanked or not has made no difference. Dr. Bentley himself in one passage says that in these decayed tracts the old river-beds become but local storm water chutes and that this decay of the river systems "has been responsible."

To summarise then up to this point, Dr. Bentley would explain the malaria in Bengal as due primarily to the embanking of the land, which prevents the natural flood and flush by river inundations. The reviewer, on the other hand, suggests that whether or not there be an embankment in the province, the incidence of malaria would to-day be as it is and that this is wholly a function of the existing state of growth of the different parts of the delta.

The second part of the author's paper is devoted to the schemes which he advocates for the amelioration of the state of affairs. They are classified according to whether they have any coincident economic value or not. The former are called, after the Italian, "bonification" The others are the "specific" anti-malarial measures.

The specific anti-malarial measures are in general dismissed as impracticable on the score of expense or that they have been tried and failed. If they were to be carried out on the same scale as at Panama they would cost from 18 to 27 crores per annum. *Drainage schemes*, he says, are in general out of the question as in the flood season the level of the rivers is too high. *Flooding* without aiming at any economic advantage (therefore not 'bonifying') has been successful in a few places. The information given regarding the administration of "*State quinine*" is very valuable and should, it seems, be reprinted for the benefit of all governments who make use of it.

The author says that all these measures are so comparatively inefficient or costly that they should only be tried to allay malaria in a lightly-infected community, when they might be partially effective.

The measures called "bonification" imply a much more fundamental policy and are needed in a highly infected decadent community. The particular measure of bonification indicated for Bengal is irrigation.

Examples are cited where attempts at bonification have been successful in other countries, particularly in Holland, the English Fens, and the Italian Val da Chiana; in Egypt irrigation should not strictly be described under bonification for it was not instituted for the purpose of allaying malaria. But as pointed out above malaria is so local in the mechanism of its incidence that the experience of one country is by no means repeated in another, nor even in the same, for some of the Italian schemes have failed.

Coming nearer home, however, the Tanjore (Cauvery), Godaveri and Kistna delta irrigation schemes covering in all some 4,000 square miles of Madras Province, are recounted as examples of what has been done by irrigation (*plus* embankment). The

* Zemindar = landlord.

† Although, as shewn above, one should not do this.

results have certainly in every way been magnificent. In Bengal itself several comparatively minor schemes have been instituted: some have been in some degree successful, e.g., the Dankuni Jelah Project and the Howrah and Rajapur schemes; others have failed, e.g., the Manikhal Khal and Magraghat drainage. The Bengal schemes were mostly put in hand for only drainage purposes but in practice the drainage outlets have been used as irrigation inlets, so that the schemes come properly under the heading of irrigation.

Apparently the author thinks that irrigation schemes for the afflicted tracts of the country will neutralise all the harm that embankments have done in preventing flood and flush, but in addition he favours the statutory prohibition of further embanking. He, moreover, considers that these schemes would have a desirable effect in the direction of improving the navigability of the rivers and so making the need for roads and railways less clamant.

Now before embarking on great irrigation schemes primarily with a view to reducing malaria, the evidence adduced by the author which bears on the problem must, as he will allow, be specially considered. In the first place, presuming such schemes to be technically practicable,* is it likely that they will be successful? Most of the irrigation schemes which have been tried certainly suggest that such would not make matters worse than they now are, even if they would not improve the situation. Projects on a big scale, however, like those in the Madras Province deltas might succeed where smaller ones have failed. On the other hand, if the malarious parts of the province are malarious only because they have been elevated, then whether watered with rain-water or irrigation water they might be equally unhealthy. It is a most striking fact that *A. aconitus*, one of the worst of malaria carriers, delights in the fast-flowing water of grass-edged irrigating channels (see plate 1), and in the Brahmaputra delta it is in the irri-

gating channels of the land above the *pathar* level that one chiefly finds *A. funestus* (= *minimus*). Moreover, irrigation water does not carry the silt which Dr. Bentley says is, such an important factor. The situation might, it appears to the reviewer, be exactly comparable to what one sees in that very district of Assam where Dr. Bent-

* The laymen in these matters may be permitted to ask whether the amount of water available for irrigating—qua flooding-and-flushing in the more elevated malarious parts of the delta will be sufficient for the purpose without so reducing that which now provides the flood and flush of the more fortunate parts that the condition of these will be rendered similar to that of the raised area. Indeed, Dr. Bentley himself says “more water might be temporarily diverted down a moribund water-way, but this result can only be obtained at the expense of other channels and may therefore do as much harm as good.”

ley was medical officer; the non-malarious “*pathar* level” subject to inundations from the Brahmaputra, and the elevated “red-bank” alluvium (see plate 2), very

malarious, where the rice-fields are intersected with little irrigation channels teeming with *A. funestus*.

Such facts are warnings that Dr. Bentley's conclusions, based mainly on the theoretical assumption that “flood and flush” is necessary to prevent malaria, may, if put into practice by irrigation not have any result. There is need for caution. Nevertheless, an irrigation scheme must necessarily have an economic value, so that not much would be lost if it failed from a health point of view. And the proceeds might, following the very good Italian custom, be earmarked for later and better anti-malarial schemes. The reviewer on this account would beg to support Dr. Bentley's proposals to Government.

On the other hand, the possibilities of drainage schemes might be reconsidered, though the reviewer admits that *a priori* not much can be hoped from them because the worse malaria carriers, like *A. funestus*, are more at home in drains than in the pools and swamps which they drain. Most of the so-called drainage schemes which have been instituted in the past have worked out as irrigation *plus* drainage schemes. The Saraswati scheme, however, was successful (see p. 118)? There should at any rate be no difficulty about providing for gravity drainage in the more malarious parts of the delta, as they are the highest parts and the old river-beds and river-bhils are at the highest points of them.

Needless to say there is very much more, which is very valuable, in the author's paper than has been touched upon in this review, but the essential points have been carefully considered. The arguments submitted against the acceptance of some of the author's conclusions as to the causes of malaria in the Province suggest the advisability of proceeding with proper caution, but have not traversed the main object of the work,—the recommendation to Government that the irrigation of the malarious tracts should be taken in hand.

Dr. Bentley's work is testimony to his Napoleonic vision and Government should be grateful to him for his spirit. No such gigantic piece of sanitary philosophy has ever before been perpetrated. The author would make a gargantuan feast of Gorgases.

"Unani" System of Medicine. Official Decision.

From *The Statesman*.

A RESOLUTION of the Government of Bengal on the report of the Committee appointed in August 1921 to consider and advise the Government as to the best steps to be taken for the restoration and development of the *Tibbi* or *Unani* system of medicine states that the Governor in Council, after a careful study of the Committee's report, is of opinion that there is not adequate justification for the expenditure of public funds on the scheme outlined by the Committee.

The Committee issued a *questionnaire* to 272 *hakims* of standing in different provinces and to members of the All-India *Tibbi* Conference but the response was disappointing. Later, it was decided to depute Major Suhrawardy and Hakim Habibur Rahman (members of the Committee) to visit different centres of *Tibbi* learning with a view to studying at first hand the method of teaching in vogue in different *Tibbi* schools. In his report Major Suhrawardy pointed out that the *Tibbi* or *Unani* system had languished in Bengal, partly owing to the decline of Moslem influence. It was suggested that the encouragement of the *Tibbi* system might provide a cheap and yet sufficiently skilful type of doctor for the needs of the Mohammedan community in rural areas and might provide employment for many of the Maulvis who, after a course of study at the Madrasahs, have difficulty in finding a market for their wares.

The Committee then made certain proposals which briefly stated, are as follows:—

(1) The establishment of *Tibbi* schools in Bengal to be associated for clinical training with the recognized Government medical schools of the province; (2) the provision of scholarships for the purpose of sending selected students to the *Tibbi* colleges at Delhi and Lucknow, these scholars being bound by agreement to enter a rural medical service or to practice in rural areas with the help of subsidies to be granted by local bodies, on the completion of their course; and (3) arrangements for post-graduate training of students qualified in the *Tibbi* system, under well-known *hakims* in different parts of India.

DEFECTS OF PROPOSALS.

The chief defects of these proposals, the resolution points out, is that they are designed to produce a class of practitioners following a system of medicine which admittedly requires to be supplemented by a study of such vital subjects as midwifery, gynaecology, surgery, bacteriology and the whole science of preventive medicine. The proposals, moreover, aim at giving a mere smattering of the Western system to students who in educational qualifications are much inferior to the type of students now seeking admission to the recognized medical schools. The Government have deliberately set themselves to promote the spread of Western medical science, and have taken steps to control and standardize the training and examination of medical students in Bengal. Many private schools, which had neither the means nor facilities to train and qualify students for general medical practice, have been closed, and a high standard is gradually being built up. It would not be possible to introduce *Tibbi* students into the recognized medical schools for clinical training and the Governor in Council is of opinion that any definite recognition by the Government, such as the Committee proposes, of *Tibbi* studies will inevitably drive the Government ultimately into accepting full responsibility (involving heavy expenditure) for the continuance and development of a system which is in so many respects utterly different

from the system already transplanted with such admirable success into India.

The Government are not satisfied that there is any need to subsidize *Tibbi* studies proper, or that there is justification for the state incurring expenditure in seeking to engraft some limited knowledge of Western methods and theory on to the *Tibbi* system. And the lack of response by the general public and by *Tibbi* practitioners to the inquiries of the Committee suggests that there is no strong popular demand for an attempt to multiply the followers of Avicenna.

X-Ray Photographs sent by Wire.

QUICK *x-ray* diagnosis by eminent specialists have been made possible by telephoning *x-ray* photographs. A negative showing the bone structure of the human hand was sent from New York to Chicago in seven minutes on Wednesday, April 15th, 1925. Details were not lost in the procedure, and an accurate examination of the film was possible.

The time element in the diagnosis of an injury or ailment by a specialist is most important. In complicated fractures or other bone injuries, a quick diagnosis is invariably desirable in order to prevent infection or other complications. A saving of hours or days means everything to the patient.

During the recent tornado in the middle west, a woman received a severe fracture of the knee. The medical men available, who were not *x-ray* specialists, were unable to treat her, and it was necessary to take her to New York. If an *x-ray* film could have been sent by wire, a specialist would have been able to reply immediately with instructions for preventing permanent lameness or other complications without the necessity of going to New York. The possibility of sending the negatives by wire brings the specialist to the small community.

Fig. 1 is a reproduction of the original *x-ray* negative of the hand, sent from the laboratories of the General Electric Co. Inc. of Schenectady, New York, U. S. A.

Fig. 2 is a reproduction taken from a photograph of a positive, printed from the untouched negative as received by wire by the Victor X-Ray Corporation, Chicago.

Stibenyl in Malaria.

By Prof. Dr. TEWFIK SALIM.

(*Archiv fur Schiffs-und Tropen-Hygiene*, 1925, Band 29, pp. 183-186.)

"ALTHOUGH we have in quinine a very active specific against malaria, the question of the treatment of this fertile disease has not unfortunately been definitely solved. Under the action of quinine the non-sexual forms of the parasite disappear in most cases, rapidly and with certainty and the chief symptoms of the disease, such as fever, anæmia, enlargement of the spleen and so on. But it is unfortunately far from a *therapia sterilisans magna*; in most cases it is incapable of bringing about especially in the tropics, the disappearance of the sexual forms. The sick, in spite of a careful treatment with quinine, shelters in his body the dormant germs of infection for the transmission of the disease to healthy men. The finding of a medium which can kill gametes with certainty is of the greatest importance for the treatment of malaria. Our investigations with salvarsan and neo-salvarsan alone or with combined quinine, as also with newer bismuth preparations and yatren, carried out by my assistants Dr. Essad and Dr. Ekrem have failed to give encouraging results. The successful use of newer preparations of antimony in various tropical diseases has induced us to try them also in malaria. We have used Stibenyl in three cases of malignant tertian with quinine and obtained a quick disappearance of malignant tertian gametes from the blood."

Mahatma Gandhi and Ayurveda.

(*Indian Medical Record*, August 1925.)

IN view of the special attention the subject is receiving in this number we quote here the whole of Mr. Ghandhi's reply to Kaviraj Gananath Sen's pro-

test, as it appeared in our contemporary some months ago. Kaviraj Gananath Sen had written:—

I take this opportunity of drawing your attention to the fact that the speech you delivered when laying the foundation stone of the Ashtanga Ayurveda Vidyalaya has been greatly misconstrued both by the public and by the Ayurvedic physicians of Calcutta. May I suggest that you kindly explain that you did not mean to condemn Ayurveda itself or its conscientious votaries, but only a certain section of them who lived by fraud? To me such an explanation appears to be urgently required in view of the fact that almost all Bengali papers are misinterpreting your speech and condemning us for not contradicting it.

Mr. Gandhi's reply was as follows:—

I gladly comply with the request, the more so as it enables me to express my views about Ayurvedic medicine.

I must say at the outset that I was reluctant to perform the ceremony referred to as I was reluctant even to perform the ceremony of opening the Tibbi College by reason of the views I hold on medicine in general as expressed in my booklet *Indian Home Rule*. Seventeen years' observation has made no material change in them. If I rewrote the book, it is just possible that I should state the views in a different language. But I could no more resist the organisers of my tour than I could a bosom friend like Hakim Sahab. But I told them that my speech might prove embarrassing. Had I been absolutely hostile to the movement I should, of course, have declined the honour at any cost. But I could reconcile myself to the performance subject to the conditions I named at the meeting. I hope that the college of which I laid the foundation and to which I understand the founder, himself a Kaviraj, has devoted a princely sum, will contribute to the alleviation of real suffering and make discoveries and researches in Ayurveda that will enable the poorest in the land to know and use the simple indigenous drugs and teach people to learn the laws of preventing disease rather than curing them.

My quarrel with the medical profession in general is that it ignores the soul altogether and strains at nothing in seeking merely to repair such a fragile instrument as the body. Thus ignoring the soul, the profession puts men at its mercy and contributes to the diminution of human dignity and self-control. I note with thankfulness that in the West a school of thought is rising slowly but surely which takes count of the soul in trying to repair a diseased body and which, therefore, relies less on drugs and more on nature as a powerful healing agent. My quarrel with the professors of Ayurvedic system is that many of them, if not indeed a vast majority of them, are mere quacks pretending to know much more than they actually do, arrogating to themselves an infallibility and ability to cure all diseases. They will not study the Ayurvedic system and wrest from it the secrets which appear at present to be completely hidden from the world. They impute to Ayurveda an omnipotence which it does not possess, and in so doing they have made it a stagnant system instead of a gloriously progressive science. I know of not a single discovery or invention of any importance on the part of Ayurvedic physicians as against a brilliant array of discoveries and inventions which Western physicians and surgeons boast. In fact, Ayurvedic physicians' diagnosis as a rule consists in feeling the pulse, which I have known many to claim enables them to know even whether the patient is suffering from appendicitis. Whether the science of the pulse ever enabled ancient physicians to diagnose every known disease, no one can tell. But it is certain that the claim cannot be sustained at the present moment. The only thing Ayurvedic physicians can safely claim is a knowledge of some vegetable and metallic drugs of great potency, which some of them succeed in administering for diseases they only guess and therefore often with much harm to their poor patients. The advertisement of medicines that excite animal passions

adds immorality to incapacity and makes those who resort to these practices a real danger to society.

I know of no association of Ayurvedic physicians that protests against or endeavours to check this ceaseless flow of immorality which is sapping Indian manhood and making of many old men monsters, living merely to satisfy their lust. Indeed, I have known such physicians enjoying a status or respectability in medical society. Whenever, therefore, I get an opportunity I seize it to drive the truth home to the physicians Ayurvedic and Unani, and plead for truth, humility and patient research. I am a lover of all that is ancient and noble. I believe that there was a time when Ayurvedic and Unani medicine served a noble purpose and was progressive. There was a time when I actively helped these physicians and believed in them. But experience has undeceived me. I have been grieved to find arrogance and ignorance among many such physicians. It hurts me to find a noble profession being prostituted for making money. I have written this not to condemn individuals. I have merely reduced to writing the impression that has been left on my mind by a long course of observation of the practice of Ayurvedic physicians. It is not an answer to say, as has been said, that Ayurvedic physicians have copied the evils I have named from their Western brethren. A wise man copies not what is bad but that which is good. Let our Kavirajes, Vaidyas and Hakims apply to their calling the scientific spirit that Western physicians show, let them copy the latter's humility, let them reduce themselves to poverty in investigating the indigenous drugs and let them frankly acknowledge and assimilate that part of Western medicine which they at present do not possess. Let them shun the irreligion of the Western scientists, which in order to heal the body and in the name of science, subjects the lower animal kingdom to the hideous tortures which pass muster under the name of vivisection. Some will retort that there is warrant for vivisection in Ayurveda. If there is, I am sorry. No warrant even in the four Vedas can sanctify sacrilege.—(Young India.)

The Rockefeller Foundation.

REVIEW OF WORK IN 1924.

By GEORGE E. VINCENT.

President.

THE YEAR IN BRIEF.

DURING the year 1924 the International Health Board, the China Medical Board, the Division of Medical Education, and the Division of Studies of the Rockefeller Foundation (1) underwrote to the amount of \$350,000 a plan for publishing an international abstract journal of the biological sciences; (2) began issuing bulletins which report progress in medical education in many countries; (3) helped to spread internationally knowledge about medical equipment and teaching methods through surveys by staff members, commissions of scientists, visiting professors, and travelling fellows; (4) hastened developments in the medical schools of the universities of Oxford, Cambridge, Edinburgh, Wales, Montreal, McGill, São Paulo, Hongkong, and Siam, and of the American University at Beirut; (5) maintained a modern medical school and teaching hospital in Peking; (6) aided three other medical schools and 17 hospitals in China; (7) helped to improve the teaching of physics, chemistry, and biology in two Chinese and nine foreign institutions in China and in the Government University in Siam; (8) had a part in the development of professional training for sanitarians and hygienists at Harvard University and in schools and institutes in London, Prague, Warsaw, and São Paulo; (9) gave funds for nursing education at Yale University and in schools and hospitals in Brazil, France, Yugoslavia, Poland, and the Philippines; (10) kept a mobile staff on guard against yellow fever in Mexico and Central America; (11) at

the request of Brazil joined in an attack upon this disease from 11 centres along the northern coast; (12) helped to show the possibilities of malaria control in 13 American states and made malaria surveys or studies in Haiti, Porto Rico, Nicaragua, Brazil, Italy, Palestine, Queensland, and the Philippines; (13) either continued or began anti-hookworm work in conjunction with 32 states and countries in the West Indies, Central America and Mexico, South America, Europe, and the Far East; (14) contributed to the budgets of rural health services in 207 counties in 24 American states and in New Brunswick, Brazil, France, and Czechoslovakia; (15) continued to aid the epidemiological intelligence service of the Health Section of the League of Nations; (16) contributed to the League of Nations' international study tours or interchanges for 99 health officers from 20 countries; (17) provided directly or indirectly fellowships for 864 individuals of 33 different nations; (18) lent staff members and made minor gifts to many governments and institutions for various kinds of counsel and aid; (19) assisted mental hygiene projects both in the United States and in Canada, demonstrations in dispensary development in New York City, the growth of anti-tuberculosis work in France, and other undertakings in public health, medical education, and allied fields.

For the present, effort is centred on public health and medical education, but the trustees keep steadily in mind the possibility that in time other things may also offer opportunities. Concentration in any field is not interpreted as permanent or rigid.

The Foundation seeks direct relations with responsible agencies which are charged with carrying on a given work for the future. This means, of course, that nothing is undertaken until a careful first-hand study has been made by representatives of the Foundation. Thus when field demonstrations of disease control are made the International Health Board deals only with government agencies. So, too, plans for medical school development are carried out in conjunction with permanently established universities. Moreover, the Foundation expects governments and universities from the outset of a common undertaking to make a contribution in money or its equivalent in facilities or services. That is, aid is conditioned upon a substantial contribution from other sources. Again, help is given only for demonstrations of innovation and improvement. The Foundation takes no interest in the merely quantitative expansion of routine activities. There must be promise of qualitative advance in a given piece of scientific, administrative, or educational work.

There is another guiding principle of the Foundation. It withdraws entirely from a project as soon as this has become self-directing and self-supporting. In the case of a medical school or institute of hygiene project, as soon as the university or government has complied with the conditions the Foundation pays its share and has no further responsibility. It scrupulously refrains from all intervention in the administration of the institution.

Many excellent medical schools in influential centres have plans for improvement but lack the necessary funds to carry them out. Governments do not ordinarily lavish money on science and professional education. Private donors are sometimes hard to convince. An institution thus gets on a dead centre. An outside force is needed to set things going. To give such an impetus is precisely what the Foundation can frequently do. A representative is invited to visit a significant school and with dean, faculty, and trustee representatives, to go over its needs and plans. He has no preconceived scheme to urge but often out of his wide experience in many countries he can make useful suggestions. A programme is finally agreed upon tentatively. The Foundation promises to give a certain sum toward buildings or endowment or both, provided the institution will secure from other sources a specified amount, or provided a government will agree to increase the annual budget of maintenance to a designated new level.

During 1924 several contingent arrangements with medical schools were in process of fulfilment. Payments

were made to the University of Edinburgh toward the endowment of a chair of surgery, to the University of Wales for the development of the department of medicine at Cardiff, to Oxford University for the proper housing and support of biochemistry, to McGill University, Montreal, for the endowment of a university chair of medicine, to the University of Hongkong for endowment of a chair of obstetrics, and to the University of Montreal for the continued support of premedical teaching.

The Peking Union Medical College is a modern medical centre in the capital of China, to which reference has already been made in the *Indian Medical Gazette*.

The members of the medical faculty and their assistants number 79 of whom 41 are foreigners and 38 Chinese. The teachers are graduates of 40 medical schools and represent 9 different countries. There are besides 25 teachers in the premedical and nursing schools.

The Peking Union Medical College seeks to serve the best interests of the Chinese people, in harmony with national purposes and ideals.

The trustees hope that the time will come when the College and Hospital may be put under Chinese control and be made an organic part of the Chinese system of education.

In October 1924, the students numbered 208 and were distributed as follows: medical school 62, school of nursing 20, premedical school 60, graduate and special students 66. The graduate registration was incomplete.

In one respect the Peking Union Medical College is unique. Its staff members devote all their time to the service of the institution. They do not engage in private practice. In consequence the faculty has developed a spirit of team-work which at once strikes the visitor from abroad. A considerable amount of excellent investigative work is done each year.

Probably three-quarters of all doctors to-day are general practitioners, that is physicians whose aim it is to recognize diseases, to deal with all the more common maladies by advice and treatment, and to know when to refer patients to specialists.

There are people who assert that this type of physician is doomed; that he will disappear because he cannot compete with the specialist on the one hand and with preventive and social medicine on the other.

Such an outcome is to be viewed with concern. The well-trained, properly equipped, experienced general practitioner of ability, character, and personality is a fundamentally valuable person. He is a good diagnostician. He sees his patient as a whole. He knows his peculiarities and circumstances. He can decide when to refer him to a specialist and when to protect him against the very real danger which is threatened by a narrowly specialist point of view. He cheers and encourages, warns and commands. He is not only a physician but a friend and counsellor. The disappearance of the general practitioner would be a serious loss.

He will survive only if he can win confidence and make a living. But he will have to meet the new conditions. He will have to submit to a measure of team-work in the use of laboratories and other resources; he will be compelled to recognize the public demand for sharing costs of sickness and, most important of all, he must become a practitioner of preventive medicine, a counsellor of health, a man who can recognize and correct the minor but remediable physical and mental defects which are so common. This will mean an increasing preoccupation with the normal and a knowledge of the effects upon health of diet, exercise, mental attitudes, recreation, and family and social life. To train men and women for this reinterpreted and redirected function the medical schools will be compelled radically to modify their aims and methods and to "permeate the curriculum with the preventive idea."

In spite of the progress of public health work the medical schools have too generally neglected or slighted the preventive side of medicine. This has had an unfortunate result. The average physician fails to see as clearly as he should that he is a vital part of the public health

organisation, that he is expected to discover and to report communicable diseases, to instruct his patients, to support the local authorities, to help to create sound public opinion.

The successful teaching of hygiene to medical students will increase the number of well-trained persons who choose this field as a career, but no undergraduate course can fit men and women for specialized service in preventive medicine. This has become a recognized profession which demands appropriate training in the nature and causes of communicable diseases, methods of controlling them, sanitation, various aspects of hygiene, mental as well as physiological, vital statistics, sanitary laws, organization, and administration. Work in laboratories, library, and lecture rooms must be supplemented and applied by practical experience in the field.

To provide this varied and intensive training special graduate schools and institutes of hygiene have of late been newly created or expanded in the United States, Canada, England, in Europe and South America. In 1924 the Rockefeller Foundation, on the initiative of the International Health Board, made an additional gift of \$400,000 to Harvard University for its School of Public Health, granted an interim appropriation for expenses of the London School of Hygiene and Tropical Medicine while its new building is being constructed, continued payments toward the building of institutes of hygiene in Prague and Warsaw, contributed to the maintenance of an institute of hygiene in São Paulo, Brazil, and pledged \$650,000 to the University of Toronto for the expansion of its School of Hygiene and Public Health.

During 1924 the income accruing from investments was a little more than eight millions.

The expenditures in 1924 were:—

I. Public Health ..	\$3,195,951
II. Medical Education ..	\$3,225,027
III. Miscellaneous ..	\$700,663
IV. Administration ..	\$167,181
Total ..	\$7,288,822

Inguinal Hernia: Report of 100 Operations on Korean Patients.*

DR. A. I. LUDLOW, reporting his observations in 100 cases of inguinal hernia, in the *China Medical Journal* of March of this year gives the following historical reference to hernia in Korea.

"There is a book about 150 years old (1777 A.D.) called the *Tong Wec Paeu Kam*, written at the request of the king, by a Korean named Haw Choon entitled, 'A valuable Treatise on Oriental Medicine.' It is still much used by native doctors, who regard it as a reliable source of information both for medicine; and for acupuncture, one of their main forms of surgery. In searching this book for references to hernia, the following chapter was found (the diagnosis in brackets are my interpretation):

'Seven Diseases of the Inguinal and Scrotal Regions.'

1. *Cold Disease (Orchitis)*.—The testicle is hard as stone and very painful. This is caused by exposure to cold wind or snow. It is also due to illicit intercourse. If not cured, sterility results.

2. *Water Disease (Hydrocele)*.—The testicle is swollen like a cyst and looks like crystal. This condition is due to excessive use of alcohol, also to exposure to the wind after perspiring. Treatment: use a cathartic for expelling the water.

3. *Muscle Disease (Gonorrhoea)*.—Swelling of penis, discharge and ulceration are among the symptoms noted. Treatment: diuretics.

4. *Blood Disease (Bubo)*.—In both inguinal regions there is a swelling which looks like a small yellow melon. The common people call it a boil. It is due to the

* Article No. 36, Research Department, Severance Union Medical College.

blood settling after heavy labour in the spring or summer. It may also be due to an improper discharge of semen. When it ruptures there is a small amount of pus and blood. Treatment: medicines to stimulate the proper circulation of the blood.

5. *Air Disease (Bubonocela?)*.—This condition may be inherited, especially if the father is old. A swelling appears whenever the person cries or becomes angry. Treatment: puncture with the Chim (Korean needle) and let the air out. Another method of treatment is to give medicine to 'spread out' the air.

6. *Fox Disease (Reducible Hernia)*.—The swelling has the appearance of the rounded surface of a Korean 'male' tile. (The tiles of a Korean roof are termed 'female' and 'male' tiles; the female tile is concave and the male tile convex.) The mass disappears into the abdominal cavity when a person lies down, but when the person stands up or walks it comes out and goes down into the scrotum. This is like a fox which comes out of its hole in the daytime and goes back at night. This disease is somewhat similar to the air disease (No. 5).

7. *Enlargement of Scrotum (Massive Hernia or perhaps Irreducible Hernia)*.—The scrotum varies in size from a quart to a gallon measure. There is no pain or itching but a sensation of puffing on the cord and testicle. The swelling appears at birth in some cases. This disease is due to dampness. Treatment:—Medicine for drying the dampness. This same disease occurs at times in women (pudendal hernia).

The Korean author mentions that he has obtained his information from ancient Chinese medical books.

It seems fair to assume from the above descriptions that inguinal hernia has been known for centuries in Korea, but no mention can be found of treatment by mechanical appliances, or by operation other than puncturing with the "chim" (Korean needle).

Summary.

Sex. All the patients were Korean males. No case of inguinal hernia in a Korean female has been observed by the author.

Age. From 2 to 84 years, average age, 32.7 years.

Occupation. Labourers and farmers constitute 50 per cent. of the cases.

Duration of hernia. Four days to 45 years.

Congenital hernias, 12; acquired, 88.

Position of hernia. Right side, 62; left side, 28; double, 10.

Cases of oblique (indirect) hernia, 91; of direct hernia, 9.

Reducible hernias, 79; irreducible hernias, 9; strangulated hernias, 12.

Operative procedure.

Anesthesia. General in 80 cases; local in 20.

Type of operation: modified Bassini with transplantation of cord in 60 cases; cord not transplanted, in 40 cases.

Healing of wound. *Per primam*, 97 cases. Stitch abscess in 2 cases. Parts infected before operation, one case.

Number of days in hospital. Average, 19.6; after operation, 17.6.

Condition on discharge. In 87 cases wound healed and patient in good health; in 12 cases wound healed, but there were complications. One patient died in hospital.

"Follow up." Forty cases were followed up. Recurrence was found in one case.

Localised Gangrene following the Hypodermic Administration of Calcium Chloride.

By M. G. SEELING, M.D.

Jl. American Med. Assoc., May 9th, 1925, p. 1413.

THE administration of calcium chloride is almost the only new line of attack against postoperative bleeding in jaundiced patients that has developed during the last

decade. This drug is now in general use as a prophylactic against hemorrhage complicating obstructive jaundice. Walters came to the conclusion that three intravenous injections of 5 c.c. of a 10 per cent. solution of calcium chloride should be administered to jaundiced patients before operating on them. He advises that one injection be given daily for three days, immediately preceding operation. He advises that the solution be injected slowly, and he also calls attention to the work of Cushny, who showed that in large doses calcium is poisonous, tending to bring the heart to a standstill.

A 17-year old girl who was known to have a very long clotting time had received three intravenous injections of 10 per cent. calcium chloride before operation. After the administration of the last injection her clotting time, which had been eleven minutes, was lowered to one and one-half minutes. After the third injection, she complained of discomfort at the site of injection. This was followed by redness, swelling and the other signs of cellulitis, and finally ended in two ugly looking gangrenous sloughs that required about eight weeks to heal. Inquiry failed to disclose that there had been any particular difficulty in making the intravenous injections, although the intern believed it quite possible that some of the solution may have been injected into the subcutaneous tissue when the third dose was administered.

A series of four guinea-pigs was used to test the effects of calcium chloride when injected subcutaneously. Under aseptic precautions, 1 c.c. each of 1, 2, 3 and 5 per cent. solution of calcium chloride was injected under the skin of the abdomen, at sites far removed from one another. In every instance the 5 per cent. solution caused sloughing and gangrene; the 3 per cent. solution likewise, invariably caused gangrene, but of a less fulminant type than that which followed the use of the 5 per cent. solution; the 2 per cent. solution caused a marked induration, with an inflammatory reaction that in only one instance ended in actual necrosis; the 1 per cent. solution caused no inflammatory reaction, aside from a mild induration. But in view of the ever present possibility of subcutaneous leakage during intravenous administration, it would seem to be wise always to regard hypertonic calcium solution as a potential factor in the causation of localized gangrene. Since a 1 per cent. solution does not produce necrosis when placed in the subcutaneous tissues, and since subcutaneous instillation is likely to occur accidentally, even with the practice of the most careful technic, it is recommended to administer 50 c.c. of a 1 per cent. solution from a gravity flask, rather than 5 c.c. of 10 per cent. solution from a syringe. An added advantage of this method lies in the fact that the administration is necessarily slower than by the syringe method, thus protecting against possible cardiac depression.

The Treatment by Aspiration and Mobilization of Traumatic Joint Effusions.

Walter M. Bricker. (*Amer. Journ. of Surg.*, February 1925.).

For several years it has been the author's practice to treat traumatic synovitis by prompt aspiration and early movement. Particularly is this method useful in the case of the knee-joint, and he describes the procedure as being as simple and safe as aspiration of the pleural cavity. Neither reaction nor infection has followed any joint aspirations, performed with ordinary aseptic technique.

The method of treating a recent traumatic synovitis of the knee is as follows: The joint is emptied as completely as possible and firm pressure applied by a bandage, which allows only a slight range of movement. The patient is kept in bed or allowed on crutches, and at the end of twenty-four to forty-eight hours the dressing is removed and free movement allowed. If effusion recurs, a second aspiration is performed, followed by further bandaging. If at the end of a week there has been no reaccumulation of fluid, weight bearing is permitted and

gradually increased. Any return of the effusion indicates the necessity for further aspiration and rest. When the injury is of older standing, aspiration with immediate weight bearing is advised, provided that the fluid is moderate in amount and that little blood is present.

All cases should be X-rayed to exclude a possible fissured fracture of tibia, femur or patella.

An address on the Importance of Exploratory Incision in Cancer of the Breast.

By DUNCAN C. L. FITZWILLIAMS, C.M.G., M.D.,
Ch.M., F.R.C.S.

British Med. J., May 23, 1925, p. 953.

THIS address deals in an authoritative manner with a subject of extreme importance. The extracts which are given below contain most of the outstanding points.

The signs and symptoms of cancer of the breast are all due to extension of the growth. Fixity of the skin is the earliest sign of malignancy, it is the most suspicious and significant. It may develop in about two months, but Gross states that it is usually about fourteen months before it is developed.

A cancer may become well established before even puckering, wrinkling, and anchoring of the skin develops at all. There are other conditions, too, in which it is found: old fibro-adenomata, chronic abscess, tuberculous masses, and occasionally in chronic mastitis.

Retraction of the nipple is the next sign of importance, and this, again, is quite inconstant. It is present early in cancer which starts near the nipple, and is absent till quite late, and may never develop, if the cancer starts at the periphery of the gland. Another important fact is that in the rapidly growing carcinomata the opposite may occur, and the breast become prominent and the nipple protrude, while it is well seen in the less malignant and more atrophic forms. It is also present in any chronic condition in which fibrous tissue forms, so that it is met with in chronic abscess and chronic tubercle.

Enlargement of glands in the axilla is of small significance. Cancer can hardly grow without being accompanied by chronic mastitis, and chronic mastitis nearly always causes enlargement of the axillary glands. In addition every form of inflammatory change will cause enlargement of the glands in the axilla, and therefore very little reliance should be placed upon this sign. Far more important really is the feel of those glands; small but very hard glands are far more significant than large ones.

Often enlarged glands can be felt in connexion with cancer of the breast, and yet when examined after the operation nothing malignant is found in them. On the other hand, during the operation small glands are sometimes found right up at the apex of the axilla, which are not enlarged, but yet are infected.

Age is a great factor in diagnosis; sometimes, however, it is misleading. There is the general impression too that carcinoma hardly ever occurs in people under 35; nothing, however, could be more misleading. Several cases have occurred in the teens.

There are three different classes of cases. In the first category there is the patient who obviously has cancer. The next category is where there is a definite mass in the breast, the nature of which is doubtful. There is no infallible guide: skill, experience, common sense, and that curious faculty we call intuition, all come to our aid in a way it is impossible to explain.

It is estimated from large numbers of collected figures from various sources that 80 per cent. of all tumours of the breast are malignant and 20 per cent. innocent. That is a proportion of 4 to 1 in favour of malignancy. These figures are not quite accurate; they are derived very largely from hospital records. Probably 70 per cent. are malignant and only 30 per cent. innocent.

It is only safe to regard all tumours as malignant until we have proved them innocent. The presence of pain in a small growth is very much against the mass being

cancer; similarly, but to a less extent, is the presence of pain on handling the mass. Inflammatory masses are often more or less painful or tender. Many do not seek advice for tumours because, as they are painless, no alarm is caused. The presence of masses in both breasts is against cancer and in favour of interstitial mastitis; cancer very seldom starts in both breasts at once.

A small cancerous mass is quite as impalpable to the flat hand as is chronic mastitis. Moreover, chronic mastitis may be present in which cancer is starting, but has as yet none of the characteristics of cancer.

The margins of a scirrhus are usually much better defined than those of an inflammatory mass. This, however, does not hold good if the scirrhus is rapidly extending, while sometimes the edges of a chronic abscess are remarkably well defined.

Dimpling or the slightest adhesion of the skin, as already stated, is very much in favour of malignancy, but is not pathognomonic. The hardness of a scirrhus is rarely attained by any other tumour, but sometimes the mass is too deeply situated for this to be made out, and hardness can easily be simulated by a tense cyst. Enlarged veins seen coursing over the tumour are in favour of malignancy.

Lastly, there is the important fact that cancer rarely takes origin at the time of lactation; it does so sometimes, we all know, but it is rare, while this is the favourite time for inflammatory conditions to start.

An exploratory incision should be made before performing the radical operation, else serious mistakes will be made.

The third category is the one to which our attention is especially directed. Here there is only an indefinite lump. We may suppose it is deep seated in a voluminous breast so that nothing definite can be made out. Examination prompts us to say that there seems to be a vague thickening in the breast that should not be there, but beyond this there is nothing whatever to be felt. There is not even the certainty that there is anything, beyond perhaps something that feels like a slight mastitis: signs and symptoms of malignancy do not arise.

Six or eight months pass, and now there is a mass for sure; perhaps the skin does not slide over it quite so freely, but if the mass is deep-seated and the person is fat the skin may be quite free, so that even yet there is no sign of malignancy. Perhaps the practitioner suggests a consultation, not as necessary really, as you have already committed yourself by saying the condition is nothing, but merely advisable; the patient demurs—she feels so much better, the liniment is doing her good, she is sure the lump is smaller; and in this way ten to twelve months may have passed before a consultation is arranged and an operation suggested.

We acquit the lump of being cancer merely because it was small, had not spread and infiltrated the tissues sufficiently to enable us to say that it was malignant. We have been oblivious to the obvious fact that cancer must begin in a microscopic area and has at first no sign of malignancy, and we have forgotten the 2½ chances to 1 that it was malignant to start with; we have failed to treat the condition as malignant until it was proved innocent. Many writers have endeavoured to calculate the average time the mass has been suspected before it comes to the surgeon, and different observers have varied from a year to thirty months as the time lost.

We watch such cases carefully, but it means, in blunt English, that we do nothing except waste time.

The John Hopkins School teaches that the development of any malignant sign whatever diminishes the patient's chance of cure by 25 per cent. The best results of operations at the present day are 39 per cent. living and well at the end of five years, 61 per cent. dead or dying. Probably not 20 per cent. of the hospital cases are alive and well at the end of five years.

A woman of 50 years old with this indefinite thickening and no more should have the suspected mass removed and examined under the microscope by an expert. If it proves to be simple we have now good authority for saying so which we never had before. If it proves to be malignant it can be removed at a time when she has the greatest possible chance of cure.

A circumferential incision can be made in between the breast and the chest wall, the breast turned upwards, and the mass removed from the back of the breast. Radiating incisions are made outwards from the nipple, and the piecrust-shaped piece removed. The edges are seared with a cautery to prevent the escape of cancer cells in the event of its proving to be a carcinoma; the raw surfaces are sewn up and the breast replaced. The nipple is not interfered with, and there is no visible scar left. If preferred the pathologist can be present, and by means of a freezing microtome examine the mass then and there, and if necessary the complete operation can then be proceeded with in the event of the mass proving to be cancer. The more methodical examination in the laboratory enables a truer estimation to be formed. In these early cases, the whole mass must be carefully searched and any suspicious piece cut separately. The search must be carried out by a skilled person; it cannot be done by the laboratory boy.

If operations for cancer of the breast could be carried out at this time there is no reason why we should not have 75 per cent. alive and well at the end of five years.

In the last twenty years the operation on the breast has quadrupled its gravity. The extent of the operation has reached its limit, and if our results are to improve, it must be by earlier diagnosis, along the lines just indicated.

The Etiology of Malignant New Growths.

By C. C. TWORT, M.D., B.Ch. (Aberd.).

The Medical Press, July 29, 1925.

"In a paper bearing the above title, which appeared in the *Lancet* of July 18th, 1925, Gye claims to have shown that certain carcinomata and sarcomata of human and animal origin with which he has experimented are caused by filter-passing or ultra-microscopic viruses. An analysis of the paper, however, leaves one very unconvinced of the validity of the conclusions drawn by Gye from the experiments performed by him, with one or two exceptions.

Rous showed that the sarcoma of the fowl, which bears his name, is caused by a filtrable virus. This is confirmed by Gye, and furthermore the latter worker has performed experiments which go to show that sarcoma 37/S of the mouse is due to the same category of parasite. The conclusions drawn from these experiments would appear to be warranted by the results obtained, and the fact that the 37/S tumour can be transmitted from mouse to mouse by the utilisation of a cell-free filtrate is of very great interest.

Now, if we leave aside the direct 37/S experiments, which were really quite a separate group, we find that the only type of tumour produced by injection of cell-free filtrates was the Rous sarcoma in the fowl. In every case where a positive result was obtained material was present in the inoculum which had, at any rate at one time, contained living Rous virus. No other type of tumour was produced in the fowl and no tumour of any description was produced in any other animal. Is Gye satisfied that his sand filtrates and washed deposits in the crucial experiments were really free from virus? From the details given of the experiments many other workers are rather of the opinion that the sand filtrates probably still contained living virus although with a virulence attenuated by the manipulations to which it had been subjected.

According to Gye's own experience the lethal dose of the virus is proportional to the amount injected. Also, if the sand filtrate is not treated thoroughly

enough with chloroform it remains virulent, while if treated too severely with chloroform it cannot be rendered virulent by any of the means tested. Is it not probable that in the intermediate stage where the filtrate will not infect alone, but will infect on the addition of some special substance, we have another example of activation with which workers in the field of infection and immunity are so familiar? We read that the specific factor is a labile chemical substance, which fact of course increases the difficulty of the experiments; but one may ask, has the important control of obtaining the specific factor from tissues which are not cancerous or sarcomatous been performed?

In the same way the culture experiments are unconvincing. Has the experiment been performed to see whether the specific factor of a Rous sarcoma can render virulent a culture made from other than new growth tissues?

When a carcinoma in an animal has been produced by the injection of a cell-free filtrate, obtained either by filtering an emulsion of tumour cells or by filtering a culture, and with or without the addition of any non-irritating non-cellular substance, then will strong proof of the presence of a virus be given. In fact, when experiments such as those performed with 37/S can be successfully carried out with other new growths of which the primary etiological factor is unknown, then will a real advance in our knowledge of the etiology of such tumours have been made.

The question as to whether a virus is particulate or not depends upon what one understands by the word particulate, for after all the term is only relative. In any case it is well to remember that experiments have been performed with several viruses which tend to show that they are very little, if at all, larger than a protein molecule."

Post-Mortem Cæsarean Section : A Living Child.

Brit. Med. J., May 2nd, 1925.

"On February 21st Mrs. S., a Khasi patient, was admitted at about 11 a.m. in an unconscious state in an eclamptic fit.

"Before any treatment could be undertaken she collapsed quite suddenly and died about three minutes after admission. Examination showed that she was at about term, and that the child was still alive. Death was so rapid and unexpected that two minutes or more were spent in making quite certain that it was actual and not apparent. It must have been about seven minutes after death before a very hasty Cæsarean section was performed. An apparently lifeless full-time male child was delivered. Artificial respiration was undertaken with great energy and efficiency by the two European sisters attached to the hospital, and they were well assisted by the Indian nurses under training. Before the operation wound had been hastily approximated the child was crying. He had a number of slight fits during the first twenty-four hours, but has since done very well, and as we write—sixteen days later—is making excellent progress."

Puerperal Eclampsia.

By Prof. JACQUES DECOURT, M.D.

The Medical Press, August 1925, p. 111.

PUERPERAL eclampsia is a complex syndrome correlated with gravidic auto-intoxication of which the convulsion is not the sole manifestation but is the culminating point of the organism in distress. There are two special predisposing causes, viz., cold and

over-eating. Though usual, albuminuria is not invariably present.

A heightened blood pressure is an early sign which is rarely lacking. It is present even when albuminuria is absent. A pressure of 150 mm. maximum is a danger signal, and calls for milk diet. Observation of the blood pressure throughout pregnancy is therefore a *sine qua non*.

Headache is a prominent feature with perhaps somnolence, loss of memory or, it may be, restlessness, insomnia, and nightmares. Noises in the ears and visual disturbances come next.

Almost always the actual convulsion is preceded by sharp pain in the pit of the stomach, with vomiting of food or bile. At this stage the excretion of urine is much reduced, the albuminuria is abundant, the blood pressure may reach 190, 200, or even 250 mm. Failing immediate free blood-letting, we may get the grave terminal manifestation, viz., the fit.

Pathogeny.—It is now generally conceded that eclampsia is due to a constitutional intoxication peculiar to the state of pregnancy.

The exact nature of this poison is not known though its existence has been sufficiently demonstrated.

Treatment.—The best treatment of eclampsia is its prevention. In primipare regulate the diet, avoiding excesses of all sorts. Secure a regular action of the bowels, and by warm baths secure a free action of the skin. Above all we must keep a sharp look out for the preliminary symptoms. The urine should be examined once a fortnight, and in suspicious cases every other day. The same remark applies to taking the blood pressure at regular intervals. Directly we find albumen the woman is put on strict milk diet four to six pints a day, pure or diluted with Vichy water. Tarnier used to say, "an albuminuric woman who has been put a week on milk diet will not have eclampsia." Milk diet causes the albuminuria to disappear and the blood pressure to become lower. When there is no more albumen the patient is put on an achloride lacto-vegetarian diet along with rest, both physical and moral. She must avoid cold. When the inaugural symptoms present themselves she must be put on water diet or lactose water, drastic purgatives and copious intestinal lavages, and if the blood pressure be high, then venesection. She should be kept quiet in a darkened room for a time, visits being forbidden.

Curative Treatment.—There are two principal indications, viz., free bleeding and nerve sedation. Bleeding has a double action, it withdraws from the organism a certain quantity of the poison and it lowers arterial tension. We must withdraw from 800 to 1,000 c.c. We must bring down the blood pressure 4 or 5 centimetres and the minimum pressure at least one centimetre.

Chloral is the principal drug employed to soothe the nervous system and give the patient rest. We may give from 6 to 15 grammes in the twenty-four hours in divided doses. Failing chloral a centigramme or two of morphine is sometimes of service, but its use is not free from danger. During the period of the attacks strict water diet is imperative.

During the convulsive attacks we must take care that the patient does not injure herself, any false teeth should be removed; we must prevent the tongue being bitten by putting a compress or a bit of wood between the teeth. Inhalations of oxygen (or hypodermic injection of oxygen) are useful for the purpose of combating asphyxia.

Obstetrical Treatment.—In France the doctrine is to let matters as far as possible take their course during pregnancy. In desperate cases in which medical treatment has failed to relieve, the propriety of a vaginal Caesarean section may be raised.

When it comes on during labour, as soon as dilatation is complete we may have recourse to forceps or to version in order to empty the uterus as speedily as possible, but nature often does this for us without unnecessary loss of time.

After delivery we must beware of flooding. Beyond that nothing is required except the strictest asepsis in view of the special liability of such subjects to infections of all kinds, but avoiding the use of toxic antiseptics such as corrosive sublimate and carbolic acid.

Once a woman has suffered from eclampsia it behoves us to take particular care in subsequent gestations so as if possible to avert the wrath to come. It does not follow, however, that the attack will necessarily recur, for eclampsia requires a concatenation of circumstances for its production.

The Ayurvedic Treatment of Rabies.

The Journal of Ayurveda, August, 1925, p. 76.

To

THE EDITOR,

JOURNAL OF AYURVEDA, CALCUTTA.

SIR,

May I be allowed to make some comments on matters relevant to Kaviraj Shivanath Sen's last article on the Ayurvedic treatment of rabies in the July number of the "Journal of Ayurveda."

When Pasteur's antirabic treatment or one of its later modifications is employed by Western practitioners they do not speak of having "cured" so many people from dog bite (although the term might be correctly so used having regard to its derivation and real meaning), but merely of having given prophylactic treatment to so many people. They do not pretend to know whether these people actually have been infected, nor do they pretend that the treatment will certainly protect the bitten person if the latter actually have been infected. Experiments have shown that the treatment offers a considerable measure of safety to a bitten person; he is under no obligation to submit to it, the case is put to him and he can take either the admittedly imperfect treatment or the greater risk of no treatment at all.

I have myself heard several accounts of the methods employed by South Indian Vaidyans in the treatment of persons bitten by probably rabid dogs. They agree fairly closely with the method described by Kaviraj Shivanath Sen.

The principle underlying the Ayurvedic treatment is apparently that of homœopathy, that like cures like.

If symptoms which resemble to some extent those seen in hydrophobia can be produced by some artificial means in a person who has been bitten by a rabid dog, relatives will readily believe that the vaidyan has induced the disease in reality; and when the symptoms fade away, or are allayed, they will as readily believe that the putative disease has been finally cured.

Everybody knows that concoctions containing datura will produce symptoms of intoxication, but is there any evidence to show that the effects of datura on a normal person and on one that has been bitten and infected by a rabid dog differ in such a way that the one can be distinguished from the other? The effects of such intoxicants vary both with the dose and with the individual, and I do not think that any one could prognosticate with certainty what would happen in the case of any particular individual.

The Kaviraj says in your February number (p. 278) that if symptoms (like those seen in hydrophobia) do not appear after the initial provocative treatment "the patient can at once be pronounced as not infected," and in the July number (p. 23) he says "If among other symptoms of madness this special symptom, viz., imitation of the cry and action of the rabid dog is present, we know that the patient was infected. If this particular symptom does not appear we know that though bitten by a rabid dog he has escaped infection." There is some discrepancy between these two statements. In the first it is implied that the provocative dose of intoxicant produces no symptoms in persons who have not been infected with rabies; in the second it seems

to be admitted that the intoxicant produces symptoms of intoxication in both infected and uninfected persons, but it is only when "imitation of the cry and action of the rabid dog is present" that the diagnosis of infection is established.

The discrepancy is not of much importance: the point is this, that after dosage with mixtures containing datura or other intoxicants persons who are actually infected by a bite inflicted by a rabid dog are said to exhibit certain definite signs whereby they may be distinguished from persons who have been bitten but are not infected. Modern methods admittedly cannot distinguish between the infected and uninfected. Can Ayurvedists produce any proof, either experimental or statistical, in support of this claim of theirs which will bring conviction to any unprejudiced, trained and orderly mind? If they can, it should be done; if they cannot, their claim is without basis and falls into the category of unsupported assertions.

Whether the sign be infallible evidence of infection or not, it does not seem to be really quite so important as the Kaviraj would have us believe, except that the patient, or rather his relatives, for the patient is at this time delirious, can on its appearance or non-appearance be given a definite opinion. By the time the sign is due the patient has already endured the worst and most dangerous part of the treatment: he has been purged and made to vomit, he has eaten medicated cakes and has been intoxicated by them. It only remains to tie him up, or down, preferably in the hot sun for some hours, then to pour a huge amount of cold water over his head for a prolonged time and finally to give him cooling drinks. He would be a strange being who would not exhibit "annoyance" after being treated thus, even if he be considered to be cured. Presumably, if the sign be negative, the patient is spared the bonds, the hot sun and the cold douche, but it can scarcely be maintained that a negative sign saves him from all pain and trouble.

I am afraid that I remain unconvinced that Ayurvedists are in possession of a method of determining for certain whether a person bitten by a supposed rabid dog has really been infected or not, and whether he stands in need of treatment or not. Apparently the most dangerous part of the treatment namely, the administration of an intoxicant such as datura, must be gone through before the sign is evoked, so the sign would seem to be of little practical value.

It is extraordinary how this idea that persons suffering from hydrophobia bark like a dog and behave like a dog permeates the world. The lay public all believe it; the medical text books all relate it. I have had the opportunity of seeing as many human beings suffering from hydrophobia as any man in India. Yet never once have I heard any of them bark like a dog or give even a reasonably good imitation of a bark. The truth is that these unfortunates have their palatal and some of their respiratory muscles partially paralysed; they have difficulty in swallowing their saliva and in breathing. Every now and then respiratory spasms occur, though not in every case, and the wretched person in his endeavours to breathe and to clear his throat makes a variety of involuntary, explosive sounds which do not really resemble barks at all. Such persons also sometimes become very violent and will bite, scratch, tear at and kick anything or anybody they can reach. All their symptoms are exacerbated by the presence of a sympathetic and moaning crowd of onlookers. Sometimes in the early stages the patient will become exasperated (and no wonder) with the attendant crowd and rush at them with open mouth or snapping teeth and sundry cries, but these are early and purely voluntary exhibitions.

In the absence of any method of deciding whether a person bitten by a supposedly rabid dog has been infected or not, it is difficult to set a value on different methods of treatment. From statistics which I have collected over many years I find that the risk run by people in South India of dying from hydrophobia after

having been bitten by a supposedly rabid dog is of the order of 63 per cent., if they are untreated. It must be quite clear, therefore, that in order to put a value on any method of treatment many thousands of persons must undergo it and careful notes must be made of each case.

As far as the modification of Pasteur's treatment used in the antirabic institutes in India is concerned, we have significant figures. No figures which would be regarded as significant by a statistician can be produced which would enable a value to be set on Ayurvedic treatment, and until this can be done the exponents of modern methods are justified in remaining sceptical as to its value. Mere assertions carry no weight.

Yours faithfully,

J. B. CORNWALL,

Lieut.-Col. I.M.S.,

Director, Pasteur Institute, Coonoor.

Reviews.

MODERN MEDICINE: ITS THEORY AND PRACTICE.

—Edited by Sir William Osler and Thomas McCrae.
Vol. I. Third Edition. To be completed in 6 vols.
and desk index. Sold in complete sets only.
£12 12s. net. London: Henry Kimpton, 1925.
Pp. 845. Price, 42s. net.

THIS system of medicine was first published in 1907. The success of the first edition allowed a second to be published within six years; it is now twelve years since the first volume of this second edition was issued. Sir William Osler, the first editor, died on December 29th, 1919, so that the whole of the work of editing this edition has fallen on the shoulders of the second editor. At the time of Sir William's last illness Professor McCrae was corresponding with him as to the advisability of issuing a third edition. During the last twelve years new diseases have come into prominence and much new light has been thrown on the etiology of others. Researches in physiology have advanced our knowledge in such subjects as metabolism and the functions of the digestive tract. A new edition of this system is therefore welcome.

We are glad to see that Sir William's introductory essay on the Evolution of Internal Medicine has been retained. In this he sketches the story of the evolution of modern medicine over twenty-five centuries. It is not a story of rapid progress. Little real advance was made between the times of Hippocrates and Sydenham. There were many dark periods when the healing art was practised almost entirely by charlatans, and before any advance could be made lost ground had first to be regained, this always meant the restoration of the humoral pathology of Hippocrates.

The system proper opens with a chapter of the study of infectious diseases generally. Practically the whole of the rest of the volume is devoted to bacterial diseases; typhoid is first dealt with by the second editor. The 121 pages that are devoted to this disease constitute a very complete monograph on the subject; the photographs showing the stages of the formation and healing of typhoid ulcers are particularly instructive. Each disease is dealt with by a master on the particular subject, these for the most part come from the American continent but their names are familiar to us in this country. The chapter on Malta fever is written by Sir David Bruce and Dr. G. C. Low; both names are familiar to students of tropical medicine. Leprosy, another subject of particular interest to this country, is only allowed 10 pages, but these are written by Dr. G. W. McCoy, a former Director of the Leprosy Investigation Station in Honolulu. Tuberculosis, a subject which allows

specialisation within its own gates, is given three chapters; the etiology, the pathology and the clinical study of the disease are aspects which are treated separately each by a different writer.

It would be impertinent to attempt to criticise the book. This system already enjoys the reputation of being probably the most widely read one in the English language and if the standard of the first volume is maintained this edition can only enhance this reputation.

MEDICAL GYNECOLOGY.—By Samuel Wyllis Bandler, M.D. Fourth Edition. Philadelphia and London: W. B. Saunders Co., 1924. Pp. 930. Price, Cloth, 40s. net.

THE fourth edition of Bandler's Medical Gynecology has appeared. The average medical man regards gynecology as almost entirely surgical and will be repaid by perusing this volume and noting how extensive the medical side is. There is an excellent and detailed account of gynecological examination including the Rubin test for patency of the tubes. This chapter is profusely illustrated. Cystoscopy and renal function tests are dealt with clearly.

The chapter on endocrine glands to which are devoted one hundred and ten pages shows that the author is convinced that endocrinology and endocrine therapy have advanced *pari passu* and that substitution therapy is on a sound basis. With this view very many authorities are in complete disagreement including the authors of the pamphlet recently issued by the American Medical Association.

Constipation—although scarcely gynecology—is so fully discussed that it takes up fifty pages: and another sixty are allotted to "associated nervous conditions in gynecology." On the other hand the important subjects of Pelvic Peritonitis and Inflammation of the Fallopian Tubes—diseases which are so common and so far-reaching in their effects and in which medical treatment is so important—are dismissed in five pages each.

Redundancies are to be found—for instance the treatment of cervical erosions is given in the chapter on leucorrhoea and is repeated in the chapter on endocervicitis—so that the matter on pp. 374 and 375 is shown again on pp. 686 and 687.

The chapter on pain is well done; many will be found to disagree with the drastic treatment recommended for gonorrhoea in children, i.e., forcibly dilating the vagina with antiseptics.

There is a lot of valuable information in the work. The publishers are to be congratulated on the excellent print, illustrations and binding.

THE PRINCIPLES AND PRACTICE OF OBSTETRICS.—By Joseph B. De Lee, A.M., M.D. Fourth Edition. London: W. B. Saunders Co. Pp. 1123. Illustrations 1128. Price, Cloth, 55s. net.

THE fourth edition of the Principles and Practice of Obstetrics by De Lee has appeared—the last one being in 1921. The general lines of the former editions are followed. To ante-natal care is attached the importance it deserves, and also to the various means by which maternal morbidity and mortality can be avoided. At the same time we doubt whether it will ever be financially possible for the general practitioner, who has so often to be satisfied with a small fee for maternity work, to carry out in every obstetrical case all the aseptic precautions recommended, which include a sterile gown and mask, stethoscope fixed to the head and a plentiful supply of sterile towels, etc. It is certainly beyond the power of the midwife who does such a large bulk of normal cases. The author regards delivery to a certain extent as a pathological phenomenon and states that he has never known a woman as physically sound after child-birth as before.

There is a full account of hyperemesis gravidarum. The author points out that it is necessary in every case to clear up three points (a) that the patient is pregnant, (b) that the vomiting is toxic or neurotic or both, or reflex, (c) that the vomiting is not due to some other condition apart altogether from pregnancy. He wisely

states that "an underlying neurosis should not always be lightly assumed" and that most teachers believe all causes of nausea and vomiting of pregnancy are toxic in character aggravated perhaps by a neurotic element. He considers the urinary findings to be unreliable and tests for liver functions unsatisfactory. Regarding prognosis and treatment he emphasises the importance of getting fluid into the system and carbohydrates with bromides, recommending glucose per rectum and intravenously but omits any mention of alkalies. Insulin is mentioned. It is to be regretted that in recommending intravenously glucose emphasis is not laid on the necessity of using anhydrous C. P. dextrose and not commercial glucose which is impure and may cause grave symptoms. As to when the uterus should be emptied, it is pointed out that no definite indication can be laid down. One has to rely on one's own experience, the progress of the case, condition of the patient and the effect of treatment. This is sound advice. He also points out that if this operation is left until too late, it will do no good, as the damage is too great to be recovered from.

Eclampsia is a subject which has not advanced much in the last few years unfortunately, and the practitioner is beset by the advocates of the conservative treatment on one hand and those of the radical treatment on the other. We think that more details of Stroganoff's treatment might have been given in this huge treatise. It is summed up in twelve lines. The Dublin treatment is not even mentioned. One is left in some doubt as to whether the author advocates the conservative or the radical treatment. He favours the former for the general practitioner and if the child is not viable and the latter when the eclampsia sets in with violence, frequent convulsions and coma. He strongly condemns the use of chloroform as an anæsthetic and recommends ether instead. *Veratrum viride* is condemned. He states that eclamptic mothers should not be allowed to nurse their babies for several days as he considers the milk may cause convulsions in the child.

In a note under the action of dietetics he states that eclampsia is rare in the tropics and among vegetarians. Our experience in Calcutta is that eclampsia is common amongst Bengalis whose diet is mainly composed of rice and fish, and rare amongst Anglo-Indians and Europeans whose diet is very much richer in protein. It is regretted that no help is given to the practitioner to enable him to classify any given case as mild or severe, and we think some note might have been made of the efforts of British obstetricians to have this classification made. The history, pathology and symptoms are fully described.

Abruptio placentæ is a term suggested by the author for use instead of accidental hæmorrhage both concealed and revealed. The causes of toxæmia, diseases of the endometrium and traumatism are fully discussed, although it is explained that the commonest condition is purely external hæmorrhage; the account under symptoms, diagnosis and treatment is almost entirely devoted to concealed hæmorrhage for which the author recommends the use of a De Rube's bag and a tight binder with pituitrin; and if the cervix is tightly closed, Cæsarian section, followed if necessary by hysterectomy.

The usual method of separating concealed (or combined) accidental hæmorrhage from external accidental hæmorrhage as regards symptoms and treatment is we think preferable to the author's.

There is an excellent account of syphilis in relation to obstetrics with some beautiful illustrations. Its protean nature is emphasised. The author states on the authority of Esch and Stühmer that the Wassermann reaction is unreliable in pregnancy and the early puerperium. He also recommends that all "laws"—Profetas and Colles's law—should be discarded and the subject studied anew.

Diseases of the heart in pregnancy are thoroughly dealt with as regards the pregnancy and during labour and also as to how prognosis may be made.

The chapter devoted to Cæsarian section is beautifully illustrated and the steps are clearly and distinctly described. For the ordinary classical Cæsarian section the author recommends closing the uterus by means of No. 2

twenty-day catgut in 3 layers to oppose the cut muscle and another layer or even two for the peritoneum.

The Porro-Cæsarian is also described, he peritonises the cervical stump and closes the skin wound.

The author's particular preference is for a cervical Cæsarian section or laparo-trachelotomy—in this the lower uterine segment only is opened. This is defined as having an upper boundary marked by the peritoneum becoming adherent to the uterus. A large transverse sinus is present and the muscle of the uterus suddenly becomes thicker. The abdomen is opened a little lower than in ordinary classical Cæsarian and the bladder is pushed down after incising the peritoneum transversely a little below the line of its adherence to the uterus—the upper part of the peritoneum is raised up and the uterus is then opened. A finger is passed into the child's mouth to bring the face forwards and the forceps are applied to the head and the child delivered. The author claims for this method the following advantages:—less danger of soiling the peritoneum, less hæmorrhage, omentum and intestine are not seen—less peritoneal shock—complications such as ileus very rare—no adhesions, rupture of uterus in subsequent labours very much rarer, a maternal mortality of only 1 in 266 cases and that it may be done after a full test labour has been tried. He does not mention the average length of time the operation takes, but it must be considerably more than in the ordinary classical Cæsarian section.

The Latzko extraperitoneal section is also described.

All through the book the author shows a marked preference for ether as an anæsthetic instead of chloroform—even in ordinary labour.

This edition is well up to the standard of its predecessors: it is profusely and beautifully illustrated. The printing and binding are excellent. It can be warmly recommended as a book of reference. Perhaps we may be allowed to suggest that if the size of the book and its price were smaller it would be more attractive to the general practitioner.

THE TOXÆMIA OF ACUTE INTESTINAL OBSTRUCTION: OR VOMITING AS A PATHOLOGICAL FORCE.—By R. H. Paramore, M.D. (Lond.), F.R.C.S. (Eng.). London: H. K. Lewis & Co., 1923. Pp. 66. Price, 5s. net.

THE author sets out to prove the thesis that increased intra-abdominal pressure, whether in pregnancy or acute intestinal obstruction, is the most potent factor in the production of the intoxication which may occur.

The ordinary view is that vomiting in acute intestinal obstruction is one of the signs of the poisoning. Paramore holds that it is the cause.

Cases are cited and evidence is brought forward to prove this thesis and to disprove the view, held by others, that "toxic proteoses" which can be isolated from the contents of the obstructed intestine, are responsible for the devastating effects of acute intestinal obstruction.

The inquiry is of the greatest importance to pathology and treatment, and the reader must weigh the evidence and decide for himself as to the issues involved.

PHYSICAL DIAGNOSIS OF DISEASES OF THE CHEST.—By Joseph H. Pratt, A.M., M.D., and George E. Bush, Ph.D., M.D. Philadelphia and London: W. B. Saunders Co., 1925. Pp. 522, with 166 illustrations. Price, cloth, 24s. net.

THE object of this book is best stated in the authors' own words:—

"This has been written in the hope of utilising the experience gained in the instruction of medical officers in physical diagnosis at the Medical Reserve Officers' Camps during the late war."

The book is admirably suited to the purpose for which it has been written.

The authors do not limit themselves to the physical diagnosis of the diseases of the chest in any narrow sense, but go in full detail into all the signs and symptoms of diseases of the respiratory and circulatory systems. The reader has not to search in books of anatomy and physiology for explanation of the text, all the pheno-

mena are fully discussed from the embryological, anatomical and physiological points of view. The illustrations are numerous and most illuminating and the style is simple and exceedingly easy to understand. For the student it is excellent and still more it is an ideal book for the medical man who has been off the irons for many years and wishes to bring his practical knowledge of physical diagnosis up to date. There is a happy combination in the authors of the clinician, the pathologist and the clinical teacher, who know by contact with post-graduate students what are the limitations of the knowledge of the average medical men and know also how to meet them.

It is impossible in a short review to give any adequate idea of how the authors have dealt with different subjects in this book of over 500 pages, but a single example will illustrate their methods. Taking up the article of auricular fibrillation, one finds the subject dealt with in 4½ pages. The principles underlying the causation of this condition are vividly illustrated in a single diagram and a pulse tracing on the opposite page makes clear the meaning of the text. First of all, the general explanation is given and thereafter under the heading of diagnosis, the whole matter is dealt with from a clinical point of view. Statistics are given which show the comparative importance and frequency of auricular fibrillation and its various causes are clearly explained.

The authors are clearly masters of their subject and the doctor who wishes to improve his power of clinical diagnosis should have this book not on his bookshelf, but close in front of him on his writing table.

EMPYEMA THORACIS.—By E. A. Graham, A.B., M.D. St. Louis: The C. V. Mosby Co., 1925. Pp. 110. Illustrated. Price, \$2.50.

THIS useful little book deals in an interesting way with a problem which the general practitioner, not less than the operating surgeon, frequently finds himself up against.

Empyema occurs so infrequently that an opportunity to study a large series of cases consecutively is seldom obtained.

The epidemic of hæmolytic streptococcus infections of the respiratory tract associated with empyema, which ravaged the military camps of America during the winter of 1917-1918 gave an unusually good opportunity for studying this disease intensively, and under proper control of a very large number of cases. The conclusions arrived at are (1) careful avoidance of open pneumothorax in the acute pneumonic stages, (2) the prevention of chronic empyema by the rapid sterilization and obliteration of the infected cavity, and (3) careful attention to the nutrition of the patient.

The larger part of the book is devoted to the description of experiments to prevent the danger of the production of pneumothorax during the acute stage.

The chief means used to prevent chronic empyema is the instillation of neutral 0.5 solution of sodium hypochlorite (Dakin's solution), which has a double power of sterilizing the cavity and at the same time removing the fibrous tissue membrane, which is largely responsible for the non-expansion of the lung on the affected side. A photograph is given of such a membrane which separated off after 6 days instillation of Dakin's solution of 200 c.c.'s at two-hour intervals along with adequate free drainage.

The book is well worth perusal by all general practitioners.

HÆMOPTYSIS IN PULMONARY TUBERCULOSIS.—By Dr. Marc Jaquierod. Translated by S. F. Silberbauer, M.D., F.R.C.P. (Edn.). London: Baillière, Tindall & Cox, 1925. Pp. vii plus 106. Price, 5s. net.

THIS little book of 106 pages is a useful addition to the already voluminous literature on the different aspects of tuberculosis. The author shows the way in which this common accident is brought about in human beings, while it is unknown in the lower animals affected with pulmonary tuberculosis. He points out that

hæmoptysis is not always a very grave symptom and that it often occurs where the healing process connected with fibrosis of the lungs has advanced to a large extent.

The remarkable thing is that bleeding from the lung into the bronchi does not occur more frequently in connection with cavity formation. This is accounted for by the fact that softening and caseation spread not so frequently from the centre to the periphery of the congested area, but from the periphery to the centre; in this way, before the whole mass separates from the healthy lung, a fibrous, limiting membrane has had time to form, thus preventing hæmorrhage taking place.

The number of remedies recommended, or at least mentioned, is good proof that none of them is very effective; prevention in the direction of avoiding strains and irregularities is more effective than any form of treatment.

The book is one well worth studying by those who take special interest in this disease, but those who have never taken the trouble to study tuberculosis, especially with regard to this pathology, may have difficulty in following some of the arguments.

A PRELIMINARY REPORT ON THE TREATMENT OF INTERSTITIAL KERATITIS.—By R. Lindsay Rea, M.D., F.R.C.S. London: H. K. Lewis & Co., Ltd. Pp. 32, 4 plates. Price, 2s. 6d. net.

THIS small book is a preliminary report showing how important the treatment of interstitial keratitis is when carried out according to modern methods, and how many of the later troubles associated with this disease such as choroiditis, nerve deafness and permanent synechia and opacities can be prevented by early treatment. This is well done and agrees strongly with the experience of the reviewer and will it is to be hoped prevent in future the ordinary remark in even modern text-books on ophthalmology, that antisyphilitic treatment has little effect on this dreadfully common disease. His remarks on the Wassermann reaction and modes of onset are brief and good. One can strongly recommend this book to all medical men in India interested in eye work, as this disease is commonly mistaken for trachoma and nebula due to ulcers and when treated, as it frequently is by irritant drugs, it can closely imitate those conditions, and its recognition and treatment especially in fairly early cases can prevent a great deal of the partial or complete blindness so commonly seen.

A SYNOPSIS OF SURGERY.—By E. W. Hey Groves, M.S., M.D., B.Sc. (Lond.), F.R.C.S. (Eng.). Seventh Edition. Bristol: John Wright & Sons, Ltd., 1925. Pp. 671. Price, 17s. 6d. net.

THIS is the seventh edition of this well-known book, which is gradually assuming the proportions almost of a text book. The author claims to have revised the entire text, and especially the chapters on abdominal surgery, with the help of Mr. D. G. Tasker. Also a number of line drawings and diagrams have been added, which considerably enhance the value of the book from the students point of view.

Whatever criticisms may be levelled against a book of this type, there can be no doubt as to its popularity among students. The practitioner also uses it freely as a book of ready reference.

ESSENTIALS OF IMMUNOLOGY FOR MEDICAL STUDENTS.—By A. F. Coca, M.D. Baltimore: Williams and Wilkins Co., 1925. Pp. 194. English Agents: Baillière, Tindall and Cox. Price, 17s. 6d. net.

THE leading works on immunology are for the most part large and suitable only for the specialist. The inclusion in recent years of instruction on immunology in post-graduate courses has necessitated the production of elementary text books on the subject. Professor Coca has written a useful little book of this type which includes everything the elementary student is likely to require. The first half is devoted to a brief account of the more important theoretical considerations, the remaining portion being a very useful presentation of the chief practical applications of immunology to medical

diagnosis and treatment. The book is well put together, and the various subjects are well described in clear language and we can confidently recommend it.

SERUM DIAGNOSIS OF SYPHILIS BY PRECIPITATION.—By R. L. Kahn, D.Sc. Baltimore: Williams and Wilkins Co., 1925. Pp. 237. Price, \$3.000.

DR. KAHN has performed a very valuable piece of research work on the subject of the serum diagnosis of syphilis by precipitation, which has culminated in the evolution of a new test now called the Kahn reaction. The test is on the lines of the Sachs Georgi reaction, the chief differences being that undiluted serum is used, rapid shaking with the antigen is employed, and the results are read off more quickly than by other methods. As is now well known the results correspond broadly, though not exactly, with those obtained by the Wassermann test. Where facilities for the latter are not available it has undoubtedly a great field of usefulness. Dr. Kahn has embodied his results in this extremely interesting book which is written in a clear and convincing manner and is altogether excellent. It should be in the hands of every specialist on the subject.

ROENTGEN DIAGNOSIS AND THERAPY.—By A. C. Christie, M.D., M.S., F.A.C.P. London: J. B. Lippincott Co., 1924. Pp. 320, with 144 illustrations. Obtainable from Messrs. Butterworth & Co. (India), Ltd. Post Box, 251, Calcutta. Price, 25s.

THIS book is a revised and enlarged copy of the author's Manual of X-Ray Technique. It has been designed as a practical guide in x-ray diagnosis and therapy for the student and practitioner.

The general style of the book, printing, and reproduction of skiagrams is excellent. The author avoids controversy and is somewhat dogmatic in his statements. Many experts in x-ray work will not agree with all he says. The book is in fact a record of the author's personal outlook on roentgenology. This, however, does not detract from its merits. There are many conclusions which will interest not only the student and practitioner but the expert as well; for instance, his defence of the Coolidge tube for roentgenography and roentgenoscopy, or his disavowal of the various chemical, photographic, and other direct methods for measuring dosage, and the adoption of the indirect method based on voltage, milliamperage, distance and filtration.

In conclusion, we are of opinion that this book should be in the hands of every practitioner as it comprises in a small space all the essential facts in the practice of roentgenology.

THE RADIOLOGICAL EXAMINATION OF THE MALE URETHRA.—By G. L. S. Kohnstam, M.R.C.S. (Eng.), L.R.C.P. (Lond.), and E. H. P. Cave, M.B., B.S. (Lond.), M.R.C.S. (Eng.), L.R.C.P. (Lond.). London: Baillière, Tindall & Cox, 1925. Pp. XVI plus 116, with 64 figs. in the text. Price, 15s. net.

IN this interesting monograph the urethra is the main subject, and the shape and relations of the base of the bladder are shown to be of considerable importance in the diagnosis of prostatic disease.

The work is intended as a guide to the methods of practice and interpretation of urethrography. The technique is fully explained. "Lipiodol" is the fluid used for injection in preference to bismuth, bromides and iodides. It is said to give rise to no irritation or discomfort. The interpretation of negatives is fully gone into and a useful chapter on normal urethrograms is given. This is followed by a section on pathological conditions.

An important point is brought out in this work, viz., when fluid is injected from the external meatus the seminal vesicles become filled. This is a point of "undoubted scientific and practical value". It demonstrates clearly the danger of applying high pressure in urethral irrigation and suggests a method of treating vesiculitis.

The work is one which should be in the hands of every radiologist and surgeon. Just as radiography has changed our views as to the anatomy of the stomach,

Dec., 1925.]

so this work gives one a new and correct view of the urethra and base of the bladder.

TREATMENT OF GONOCOCCAL INFECTION BY DIATHERMY.—By E. P. Cumberbatch, M.A., B.M., M.R.C.P., and G. A. Robinson, M.B., D.M.R.E. London: William Heinemann, Ltd., 1925. Pp. 160. Price, 7s. 6d. net.

THIS little book places on record the results obtained by the authors in the treatment of gonococcal infection. It therefore consists largely of a description of methods and records of cases. The whole range of gonococcal infections is covered including acute urethritis, cervicitis, arthritis, bursitis, fibrositis, and infection of other parts of the male and female genitalia. Most of the cases described had previously been treated by the ordinary accepted methods without success, and so particular interest attaches to the progress of these cases.

The style is easy and clear. The illustrations are ample to show the technique employed. The volume marks the greatest advance in the treatment of gonorrhoeal infection recorded in modern times.

RADIUM: ITS THERAPEUTIC USES IN GENERAL PRACTICE.—By G. H. Varley, M.D. London: Humphrey Milford, Oxford University Press. Pp. 103. Price, 6s. net.

THIS little book gives a short account of cases treated by the author with radium in the hope that it may draw the attention of the general practitioner and student to the conditions in which this valuable therapeutic agent may be of use.

The first portion of the work is devoted to a short summary of the physical problems connected with radium, including apparatus, screening, methods of application and dosage.

The second part deals with the therapeutics of radium. The list of cases includes examples of all the more important conditions for which radium is used. The author complains that he has had great difficulty in following up cases; but the records, as far as they go, contain abundant evidence of the good that can be done even with very moderate quantities of the element. It is even suggested that long exposures with moderate quantities of radium are more effective in the majority of cases than short exposures with large quantities.

It is a useful little book, if only from the point of view of directing the practitioner's attention to the diseases and conditions in which radium may help him.

ELEMENTS OF ZOOLOGY. A TEXT-BOOK FOR INDIAN STUDENTS.—By Dr. H. Hyderali Khan, F.R.C.S.E., Professor of Biology, Osmania College, Hyderabad, Deccan. Second Edition. Calcutta: Butterworth & Co., 1925. Price, Rs. 3-8.

THE book has been written for Indian students as the author informs us in the preface and is certainly meant for beginners. A certain number of mistakes are noted. The earthworm described in the text is not a *Perichata posthuma*, as noted in page 20, and the figures of the dissections do not apply to that animal. Many terms have been loosely used. A few examples may be here cited. In page 15, line 1, it is noted: "Of the Metazoa, the Coelentera are multicellular animals whose cells are arranged in a definite manner to form a covering for the body and a lining for the coelomic cavity, the *enteron*." The enteron is not the coelomic cavity. In page 7, line 4, we see: "The animal moves about by elongating its body or contracting it into a nodule." Here "or" conveys no meaning, it should be "and." In page 46, line 30, we have "A pair of styles called the *cerci* are attached under the tenth tergum." The term "style" is generally used for a second pair of process in the male; the *cerci* are present in both sexes. In page 81, line 7, we find: "behind the epicoracoids is a symphysis called the sternum, which consists of a cartilaginous anterior portion, the episternum, a cartilaginous omo-sternum." The symphysis is a form of articulation and it cannot be

the sternum. The episternum is placed in front of the epicoracoids and not behind them. There ought to have been a figure of the sternum.

The section on heredity and evolution is too short to be of any use to a beginner. This section would have been better placed at the end, as the student must have some general knowledge on the subject before he can grasp the complicated problems of evolution.

We hope the author will correct these few mistakes in the next edition. With those defects rectified the book should be a really useful one to the Indian students for whom it is intended.

ARTIFICIAL SUNLIGHT AND ITS THERAPEUTIC USES.—By F. H. Humphris. London: Humphrey Milford, Oxford University Press. Pp. 170. Price, 8s. 6d. net.

IN writing this volume the author says he is actuated by two considerations. "The first is to be of service to those practitioners of medicine who have already had their attention aroused to the possibilities of this still little known region of physical therapeutics; and the second is to awaken and stimulate the attention of those who have not given the matter the care and thought it merits."

The earlier chapters are concerned with the history of heliotherapy in general and that of ultra violet radiations in particular, a discussion of certain facts and fallacies in connection with the latter, and a description of the apparatus in common use. The therapeutics of the ultra violet rays is then considered, and their value in various skin diseases outlined. Lastly, a chapter is devoted to the uses of artificial sunlight in certain regional and systemic diseases.

This is a book of absorbing interest and fills a gap in our therapeutic armamentarium which has long been apparent.

A MANUAL OF CHEMISTRY.—By A. P. Luff, M.D., B.Sc. (Lond.), F.R.C.P., F.I.C., and Hugh C. H. Candy, B.A., B.Sc. (Lond.), F.I.C. Seventh Edition. Vol I—Inorganic Chemistry. London: Cassell & Co., Ltd., 1925. Pp. 578, with 57 illustrations. Price, 11s. net.

THIS is an admirable and well known book on inorganic chemistry. The popularity of this book is demonstrated by the fact that it has gone through seven editions. In this little volume nothing of importance to a medical student has been left out and the matter dealt with has been rendered exceedingly lucid. The authors have spared no pains to keep the students in touch with the modern theories and discoveries and we cannot but praise the masterly way in which some of the most difficult subjects, such as the electronic theory of valency, the periodic classification of the elements, etc., have been dealt with within such short compass. The questions appended to the different chapters are all well selected and the portion on Practical Chemistry at the end of the volume will be immensely helpful to students who are hampered in culling out suitable tests and methods for both quantitative and qualitative analysis from a book dealing exclusively with the subject.

Annual Reports.

ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF ASSAM FOR THE YEAR 1924
BY MAJOR J. B. HANAFIN, C.I.E., F.R.C.S.I., D.P.H., D.T.M. & H. (CAMB.), I.M.S., OFFG. DIRECTOR OF PUBLIC HEALTH, ASSAM. SHILLONG. ASSAM GOVERNMENT PRESS, 1925. PRICE 12 ANNAS.

THE birth rate, 31.04, shows an increase over last year and though higher than Bengal is lower than most of the provinces in India. The death rate 27.3 is

also higher than that of Bengal but is again lower than that of the majority of the provinces, despite an epidemic of cholera and the continual drain of endemic kala-azar.

In urban areas where registration of births and deaths is compulsory the Vaccination Inspecting Staff instituted enquiries with reference to the births and deaths, it was found that 4.54 per cent. and 3.37 per cent. of the births and deaths, respectively, had not been registered. Prosecutions were instituted but as in many cases fines of only 4 annas were inflicted little improvement is likely to be effected.

No epidemic of influenza occurred and the deaths for this disease are recorded as 169.

Cholera accounted for 19,182 deaths during the year or about one-tenth the total number of deaths for all causes.

A proposal is at present under consideration to form an "epidemic section" consisting of a small number of medical men with a subordinate personnel specially trained in water duties and rural conservancy generally. This section with its materials to be under the orders of the Director of Public Health and ready to move instantly to any affected or threatened area of epidemic disease. Such a unit with its personnel and materials will be most useful to combat epidemics, especially cholera. Cholera is endemic throughout the year in Cachar and Sylhet. All other districts reported isolated cases in every month. It only requires a slight relaxation of precautionary measures to light up an epidemic when the foci are so generally scattered. This shows the necessity for a trained staff fully provided with materials for water purification and the personnel to carry out this as well as general sanitary precautions. Reliance on the local resources is not sufficient as a rule, the latter are fully occupied with the daily duties of their station. They cannot be concentrated immediately and they cannot be expected to be as expert as an epidemic section, specially trained to deal with epidemics.

Cholera broke out in virulent form during the months of April to July and continued until the rains broke in Cachar, Goalpara and Sylhet and in the last named place again in October, November and December. Manipur State also suffered from a severe epidemic from May until September.

There was a decrease in the incidence of small-pox during the year in every district but Darrang, in this district there is opposition to vaccination in certain sections of the population.

The death rate from fevers is still above the pre-influenza epidemic rate.

In the Hailakandi sub-division of Cachar an increase of malaria was reported. It was suggested that the railway which was completed in this district in 1923 was responsible. The report of the enquiry instituted to investigate this point was as follows:—

It will be observed that the splenic indices at the villages more remote from the railway are considerably higher than those of villages much nearer. This is most significant and clearly indicates that the railway embankment with its borrow pits is not wholly responsible for the alleged increase of malaria. When the general topographical features of the country with its numerous *khals* and collections of water, together with the dense rank vegetation which is to be found everywhere, are taken into consideration, it is easy to understand that the amount of mosquito breeding taking place in the railway borrow pits is comparatively negligible and cannot very materially affect the malaria incidence. The chief breeding grounds of mosquitos, particularly the "anophelenes" are the "Baris" in which the people live. These "Baris" are situated within dense bamboo groves, where conditions for the propagation of mosquitos, such as heat, moisture, rank vegetation, numerous collections of stagnant water and the absence of sun, light and air, are ideal.

Coupled with the above is the question of insufficient supplies of quinine, which is causing an increase in the incidence of malaria. These insufficient supplies mean that patients are not getting a complete course of quini- nization and hence frequent relapses. Each time a patient has a relapse he is entered on the books of the dispensary concerned, as a fresh case. In this manner, the malaria figures become inflated and are apt to give rise to false impressions. Relapses of malaria have become more frequent during the last few years and are the result of Local Boards being unable to supply quinine in sufficient quantity to their dispensaries for want of funds. Patients are getting smaller and insufficient doses of the drug and until steps are taken to remedy this defect, malaria will increase.

Kala-azar.—The death rate from the disease again shows an increase. The number of cases treated during the last five years is 126,568, that is 7,188, 15,880, 19,659, 35,071 and 48,770 for the years 1920 to 1924, respectively.

Fortunately a remedy is now available by which it might, with confidence, be said the disease can be kept in check if not ultimately eliminated. Recent surveys have shown a widespread distribution of the disease with a marked recrudescence which unchecked would undoubtedly devastate areas, as did the more localised epidemics in the nineties which in the Nowgong area exterminated villages.

Of 48,770 cases under treatment 3,605 died. This gives a death-rate of 7.39 per cent. amongst the cases under treatment.

Six Assistant Surgeons and 81 Sub-Assistant Surgeons were employed on special *kala-azar* duty during the year.

In addition to the special dispensaries run by Sub-Assistant Surgeons on special *kala-azar* duty, all the other dispensaries in the province are required to treat *kala-azar*. All Sub-Assistant Surgeons, whether in charge of special *kala-azar* dispensaries, State or Local Board dispensaries visit and revisit villages within five miles radius of their dispensaries in search of fresh *kala-azar* cases. The cases detected during such visits are advised to undergo treatment. For areas suspected to be infected with *kala-azar* and not falling within a five-miles radius of any dispensary, special Sub-Assistant Surgeons are placed on survey duty. Suitable arrangements for the treatment of cases brought to light by such surveys are made in all cases.

A disturbing factor in the campaign is the number of "stop treatment cases" shown during the year. Out of 48,770 cases treated, 16,733 stopped treatment before the completion of their course. The ratio is about 33 per cent. Notwithstanding this the treatment is most popular, and patients eagerly come for injection.

The course of treatment with sodium antimony tartrate lasts about three months. This is rather long and tedious, and after a month or two months of injections, on cessation of the fever, and as a result of a general improvement in health, many patients discontinue their course and consider themselves cured. Unfortunately cessation of symptoms and absence of signs do not always indicate eradication of the disease which really requires a much more prolonged course.

Regulations under the Epidemic Diseases Act, III of 1897, published by the Government of Assam, compel patients to undergo a complete course of treatment. Compulsion is not always advisable or effective. To stop this unsatisfactory condition, extensive propaganda was about to be initiated in 1925, especially in schools with the aid of the Director of Public Instruction.

Leaflets popularly illustrated and written in conversational style will be read to all school children by their teachers.

The seven Assistant Surgeons on special *kala-azar* duty will deliver lantern lectures. The aim is to explain

fully the danger of ceasing treatment before completion. Treatment as carried out in 1924 consists of a three months' course of sodium antimony tartrate. The cost of this drug per patient for a course of cure was annas 3. During the year experiments were carried out at the Pasteur Institute, Shillong, with organic compounds, urea stibamine, Von Heyden 471, urea glucoside (Sic. Presumably this is misprint for stibamine glucoside) of antimony with most encouraging results. With this compound of antimony, treatment for cure is reduced to four weeks as against 3 months with the simple salt. The latest cost of one of these drugs—urea stibamine—is Rs. 10-2-0 for 3 grammes which is sufficient for the cure of one patient.

For 1925 arrangements have been made to treat all "antimony fast" cases (viz., cases which do not respond to treatment by the sodium salt) throughout the province by one of the organic compounds in selected hospitals. This will shorten the treatment by a period of two months.

It will also mean a saving of Rs. 18-12-0 per patient treated in hospital diets. The extra cost of the drug in treating with urea stibamine as compared with the sodium salt is Rs. 9-15-0, a saving of Rs. 8-13-0 is therefore shown per patient treated in diets alone, not to mention hospital accommodation, staff and clothing. It would be economically sound therefore to treat all in-door patients with urea stibamine or some similar compound of antimony in hospitals where competent medical officers are available. The toxic effects of such a potent drug and its cost at present prohibit its general use in out-door work.

Hookworm disease.—Hookworm disease is general in Assam as is shown from the returns of jails and tea gardens where examinations are made.

An extensive campaign against this disease would entail much expense. Although there may not be striking evidence of this disease, nevertheless the anemia, general debility and poor physique which result from it swell the death-rate and it is an economic handicap in the province.

Leprosy.—The Medical Department proposes in 1925 to have a special survey of leprosy in four selected districts as a preliminary move to a general investigation on, and action against this disease.

THE EIGHTH ANNUAL REPORT OF THE KING EDWARD VII MEMORIAL PASTEUR INSTITUTE AND MEDICAL RESEARCH INSTITUTE, SHILLONG FOR THE YEAR ENDING 31ST DECEMBER 1924. SHILLONG: GOVERNMENT PRESS, ASSAM, 1925. PRICE 12 ANNAS.

During the year the total number of persons who completed treatment was 1,831, of which number 94 were Europeans. Nineteen patients absconded. Twenty discontinued treatment as the dogs which bit them were certified alive and well ten days after biting; and one patient died during treatment; these forty cases have not been included in the total.

There has been a decrease as compared with 1923, of 540 or 22.7 per cent. of persons treated in 1924.

The decrease was due to the opening of a Pasteur Institute in Calcutta about the middle of the year with the result that the Bengal cases ceased coming to this Institute for treatment.

In spite of this, the number treated during the year was greater than in any previous year with the exception of 1923. A further decrease in the total number treated must however be expected in the following year owing to the above cause.

The number of deaths from hydrophobia was fourteen; of these five died more than 15 days after completing treatment. All were Indians. The total hydrophobia rate, 14 deaths out of 1,831 cases is 0.76 per

cent.; and the total failure rate, 5 deaths out of 1,831 cases is 0.27 per cent. No Europeans developed hydrophobia.

Seven hundred and sixty-four or 42 per cent. of the patients came from Bengal, as compared with 1,361 in 1923. Ninety-one cases came from Bihar and Orissa, and two from the United Provinces.

Seventeen per cent. of the cases were bitten by jackals. The hydrophobia rate for jackal bites is 1.9 per cent. as compared with 0.54 per cent. for dog bites. It would appear from the statements of patients that 745 or 29 per cent. did not come for anti-rabic treatment.

BACTERIOLOGICAL AND CLINICAL RESEARCH SECTION.

The total number of examinations was 2,530 as against 2,347 in 1923. Owing to the setting up of a kala-azar Commission with the special object of research into the method of spread of kala-azar in India and composed of Lieutenant-Colonel S. R. Christophers, C.I.E., I.M.S., Major H. E. Shortt, I.M.S., and Captain P. Barrand with headquarters at the Institute, research work in the Institute itself was concentrated on the improvement of the treatment of kala-azar by various organic salts of antimony: urea-stibamine, Von Heyden 471, and stibamine glucoside have so far been tested.

Kala-azar hospital.—The number of patients admitted during the year was 204, and 7 cases remained at the end of last year, giving a total for the year, of 211.

ANNUAL REPORT ON THE ADMINISTRATION OF JAILS OF THE BENGAL PRESIDENCY, 1924. BY LIEUT.-COLONEL W. G. HAMILTON, I.M.S., INSPECTOR-GENERAL OF PRISONS, BENGAL PRESIDENCY (OFFG.). CALCUTTA: BENGAL SECRETARIAT BOOK DEPOT, 1925. PRICE RS. 10-8-0.

Some of the principal points of interest in jail administration in 1924 are:—

Decrease in the jail population.

- Institution of Advisory Boards for the premature release of prisoners fulfilling certain conditions.
- Decrease in the number of corporal punishments. Extension of the remission system to prisoners sentenced to six months and upwards.
- Abolition of imposition of fetters for safe custody in district jails.
- Increase in the number of State prisoners under Regulation III of 1818 and *detenus* under Ordinance I of 1924.
- Influx of Satyagraha prisoners during the months of May, June, July and August.

There seems to be a progressive decrease in the jail population, the figures have been falling year by year since 1922.

Satyagraha Prisoners.—Owing to the dispute about the ownership of the Tarakeswar temple about 1,750 Satyagraha prisoners were admitted into jail. Hooghly, Bankura, Burdwan, Krishnagar and Berhampore jails were all filled with these troublesome prisoners.

The great majority of the Satyagraha prisoners were undisciplined school boys who should never have been sent to jail, few of these prisoners were above 18 years of age and some were as young as 10 years. The Satyagrahis refused to obey any rules and expected to be treated as special class prisoners. They caused disturbances in all the jails to which they were sent. It is to be regretted that some method other than imprisonment cannot be devised for this class of offenders.

State prisoners and detenus.—A marked feature of 1924 was the increase in the number of political prisoners. They comprise two classes:—

(a) State prisoners detained under Regulation III of 1818, and

(b) *Detenus* under the Ordinance of 1924.

There is no distinction in treatment between these two classes of prisoners.

It does not seem to be thoroughly understood by the general public that State prisoners and *detenus* are not sent to prison for punishment but only for safe custody. They are kept quite separate from ordinary prisoners and have a daily allowance for food which they can spend as they like. Government has provided a liberal sum of money for the purchase of books, and outdoor recreation is obtained by badminton or tennis in their own enclosure. The health of most of these men has been good and nearly all have put on weight since their detention in jail.

Warder guard.—The number of punishments inflicted on warders was 922 against 884 in the previous year. Of the punishments inflicted departmentally, the number of dismissals was 32, degradation or suspensions 7, fines 396, extra drill 154 and censures or other punishments 324. Judicial punishments numbered 9 against 10 in the previous year. Seventeen warders resigned against 30 in 1923.

Escapes and recaptures.—During the year there were 10 escapes among convicts, 1 from inside and 9 from outside the jails, 6 of whom were recaptured before the close of the year.

Numerous improvements are contemplated in the Juvenile Jail. The accommodation is at present not satisfactory and the work that they are giving is not suitable.

The number of boys under the age of 15 admitted for short terms of imprisonment, 7 days to 3 months, was 39 this year: this shows a decrease in this deplorable practice.

During the year 202 convicts were deported to the Andamans and 193 were repatriated on medical grounds.

Employment in Jails.—There is a jute mill in the Presidency Jail which employed an average of 580 convicts. The output during the year was 943,081 yards of gunny cloth as well as gunny bags, surgeon's tow, etc., that was supplied to various Government departments. In the workshops where such things as iron degchis were made, 289 convicts were employed.

In the Alipore Jail the principal industry is printing. Manufactures of chaukidari cloth and tailoring are the main employments in the Midnapore, Rajshahi and Dacca Jails.

Sickness and Mortality.—The daily average number of sick shows a steady decline and is lower this year than during any of the last five years. The death rate is also lower than the quinquennial average but higher than last year. The main causes of death are pneumonia, pulmonary tuberculosis and dysentery, these three diseases account for about half the total deaths.

REPORT ON THE STATISTICAL RETURNS OF THE PROVINCIAL MENTAL HOSPITAL IN ASSAM FOR THE YEAR 1924 BY COLONEL C. H. BENTLEY, C.I.E., K.H.P., I.M.S., INSPECTOR-GENERAL OF CIVIL HOSPITALS, ASSAM. SHILLONG: ASSAM GOVERNMENT PRESS, 1925. PRICE 8 ANNAS.

LIEUTENANT-COLONEL W. D. RITCHIE, I.M.S., held charge of the Provincial Mental Hospital at Tezpur during the year.

The total number of lunatics confined in the hospital at the close of the year 1923 was 437 of whom 352 were males and 85 females. During the year under report 70 (58 males and 12 females) were admitted into the Mental Hospital.

There was no re-admission during the year.

The total number of admissions to hospital was 143 against 222 in 1923, with a daily average sick of 32.78 against 32.92 in the previous year, the cases of epilepsy being excluded; the daily average of which was 36.19 against 34.67 in 1923.

The fall in number of admissions to hospital was due to less admissions under malaria, pyrexia of uncertain origin and under the heading "all other diseases."

The percentage of new admissions with bad health was 16.44, with indifferent health 57.53 and with good health 26.03 against 17.14, 48.57 and 34.29, respectively, in 1923. There were 22 deaths during the year against 30 in 1923. Amongst these 22 deaths, one committed suicide by hanging at night, two were killed by a criminal lunatic with the iron head piece of a hospital bedstead and one was admitted in a moribund condition with bad diarrhoea and died 21 days after admission.

It is fully recognised by Government that the accommodation in the Mental Hospital is far below requirements, and that the type of buildings is thoroughly unsatisfactory. At the request of Government a special report was submitted on the suicide and the double murder which occurred during the year and as ordered by Government rough plans and estimates have been drawn up for practically rebuilding the entire Mental Hospital, the estimate exceeding 7 lakhs of rupees.

THE ANNUAL REPORT OF THE DIRECTOR OF THE PASTEUR INSTITUTE OF SOUTHERN INDIA, COONOR. MADRAS. 1924-'25 SUPERINTENDENT, GOVERNMENT PRESS, MADRAS, 1925.

THE number of patients who were treated in this Institute during the year was 489, a decrease of 865 on the number treated during the previous year. The decrease was due to the whole area served by the institute having come under the operation of the new system whereby antirabic vaccine is issued to numerous centres for use locally. Up till about 2½ years ago all persons desiring anti-rabic treatment had to travel to Coonoor to obtain it.

Out of the total of 489 patients, 218 came from Coimbatore district although the treatment was available in Coimbatore itself.

There was an increase of 710 during the year in the number of persons treated in local centres.

The percentage of returns received is as follows:—

Patients who completed the full course of treatment	..	56 per cent.
Patients who did not complete the full course of treatment	..	5 "
No returns received	..	37 "

It is very important that the institute should know what happened to the persons treated with the anti-rabic vaccine issued. If Tanjore, which treated 165 persons, can report on 164 of them, it seems probable that districts which have sent in either no returns or only a small proportion could help in greater measure.

ANNUAL REPORT OF THE EXECUTIVE HEALTH OFFICER, BOMBAY FOR THE YEAR 1924. BOMBAY: THE TIMES OF INDIA PRESS, 1925.

A few extracts are given from this interesting report by J. E. Sandilands, M.B., D.P.H., Executive Health Officer, Public Health Department, Municipal Offices, Bombay:—

"The number of live-births registered during the year under review was 21,838, being 843 more than in

1923 and the highest on record since 1866. The birth-rate in the year per 1,000 persons living was 17.61 as against 17.20 in the preceding year.

The total deaths during the year numbered 38,774, being 815 more than in 1923 but 9,889 less than the average of the last quinquennium (1919-1923) and 3,346 less than the average of the preceding ten years (1914-1923). The death rate in the year per 1,000 persons living was 31.27.

Plague caused 409 deaths against 1,329 in 1923. The number of deaths was the lowest recorded in any year since the outbreak of the disease in the city in 1896, with the exception of the year 1920 when the deaths from plague fell to 282.

Small-pox was epidemic for 18 weeks from 10th February 1924 and caused 1,242 deaths as compared with an annual average of 494 deaths in the decennium (1914-1923). The incidence of small-pox was also severe in the adjoining districts of the Presidency.

Malaria accounted for 488 deaths as against 403 in 1923, 401 the average for the five years 1919-1923, and 313 the average for the ten years 1914-1923.

During the year the deaths among infants under one year of age numbered 9,156 and the rate of infant deaths per 1,000 of births registered was 419 as against a rate of 411 in 1923 and 478 in the ten years (1914-1923).

Compared with the decennial averages (1914-1923), the total number of deaths shows a decrease of 3,346.

Births and Birth-rates.—Excluding 1,821 still-born children, the number of births registered during the year was 21,838 and was more by 843 than in 1923 and 1,306 more than the annual mean number of births registered in the ten years (1914-1923).

The birth-rate calculated on the estimated population for 1924 was equivalent to 17.61 births per 1,000. Calculated on the census population for 1921, the birth-rate was 18.57.

The low birth-rate recorded year by year for the city is partly due to the custom whereby married women leave the city for their confinement and register their children in the *mofussil* districts where they are born. In part it is due to the fact that a certain number of births in the city are not registered.

Infant mortality.—The number of deaths among infants under one year of age was 9,156, being 524 more than in 1923, but 658 less than the annual average in the ten years 1914-1923.

The infant mortality rate expressed as the number of deaths in infants per 1,000 registered births was 419 as compared with a rate of 411 in 1923 and of 478, the annual average in the decennium (1914-1923).

On the whole it seems probable that the recorded rates for Bombay both absolutely and comparatively overstate considerably the magnitude of the rate of loss of infant life.

Of the total deaths among infants, 2,053 or 22 per cent. took place in the first week of life and 1,353 or 15 per cent. in the age-period 1 to 4 weeks.

Infant mortality by Races.—Members of certain castes appear to habitually evade the registration of the births of their children. The rate for Jains for example exceeds 1,400 and would imply that the deaths among Jain infants were nearly one and a half as many as the number of infants in the Jain community.

Among Europeans and Parsees the registration of births may be assumed to be carried out in almost all cases. Nevertheless their recorded rates exceed 170 as compared with rates of less than 100 in England in spite of the fact that the proportion of the poor and very poor in these communities is insignificant compared with that of most of the other communities in Bombay.

The high rates recorded in all communities suggest the presence in Bombay of some adverse factor in addition to the poverty and ignorance which are chiefly responsible for high rates in western countries. The

added factor affecting all classes is probably malaria; another factor which can hardly fail to enhance the infant mortality among the more ignorant portions of the population is the practice of soothing babies by the administration of opium.

Prevention of infantile mortality.—The work which is being done in Bombay for the reduction of infant mortality may be described under the following heads:—

- (i) Visits by the municipal district nurses for the purpose of getting into touch with prospective mothers and for discovering cases of sickness, especially among women and children and unvaccinated children; for inquiry into the condition of new-born infants; and for giving instruction by homely talks as to the care and rearing of children.
- (ii) Attendance on confinements.
- (iii) Provision of necessities and comforts during the lying-in period.
- (iv) Maternity Homes.
- (v) Infant Milk Depôts.
- (vi) Infant Welfare Centres.

Plague.—During the year plague assumed epidemic proportions for seven weeks from 2nd March to 19th April 1924. The number of plague attacks during the year was 450 against 1,501 in 1923. The disease caused 409 deaths in the year against 1,329 in 1923 and 1,213 the average for 1914-1923. The mortality among reported cases was 90 per cent. as against 89 in the previous year.

Plague measures.—The usual preventive and precautionary measures such as (i) inoculation, (ii) rat destruction, (iii) evacuation, and (iv) disinfection were continued during the year.

(i) *Inoculation.*—The number of inoculations performed during the year was 6,689 against 13,749 in 1923.

(ii) *Rat destruction.*—The total number of rats collected and destroyed during the year was 701,657 against 725,574 in 1923. It will be seen from the following statement that of the 701,657 rats collected and sent to the Parel Laboratory, 326,291 were examined and 3,776 were found infected, giving a ratio of 1.16 infected rats per 100 rats examined as compared with a ratio of 2.77 in 1923.

The percentage of infected rats rose from 1.01 in January to 3.36 in March and then declined gradually to 0.13 in December.

(iii) *Evacuation.*—For the reception of contacts from infected dwellings, temporary municipal health camps were established, as in previous years.

(iv) *Disinfection.*—For the destruction of fleas, all rooms in which cases of plague either in rats or in men had occurred were disinfected with Pesterine. Infected bedding is disinfected by steam.

Small-pox.—Small-pox was prevalent in the city throughout the year and caused 1,242 deaths against 479 in 1923 and 494 the average for the preceding ten years (1914-1923). The number of attacks from small-pox registered during the year was 2,097 (including 49 imported cases) against 978 attacks in 1923.

Vaccination.—There are 19 vaccination stations in the city.

The total number of primary vaccinations and of re-vaccinations performed during the year was 20,135 and 26,508 respectively as against 20,293 and 21,153 in 1923.

The proportion of primary vaccinations (13,758) in children under one year of age to the total number of births (21,838) registered during the year was 63 per cent.

Of the 218 infants under one year of age who died of small-pox during the year, 157 were not vaccinated and 4 were vaccinated during the incubation period. In the remaining 57 cases, the vaccinal condition was not ascertained.

Tuberculosis.—The number of deaths from tuberculosis was 1,568 and the death-rate 1.26 per 1,000 of

the population. Of these, 1,428 were due to phthisis (pulmonary tuberculosis) and 140 to other tuberculous diseases.

The Anti-Tuberculosis League.—The work in connection with the prevention and treatment of tuberculosis in the city, formerly carried out by the King George V Anti-Tuberculosis League, was taken over by the Municipality from July 1923. There are two dispensaries for out-patients suffering from tuberculosis.

Each dispensary is in charge of a medical officer and three nurses are employed for visiting the patients who attend, reporting on their house conditions and seeing that they follow in their homes the advice which they receive. Of the three nurses, two are employed at Princess Street and one at Foras Road.

During the year under report the total number of tuberculous patients treated at the two dispensaries was 1,302; the number treated in 1923 was 1,129.

Malarial-Fever.—There was a decided increase of malaria in September and October after the rainy season. The comparatively low rainfall and its intermittent nature may be held to account in part for this prevalence which has been so much in excess of the usual monsoon increase. For the rest the excessive incidence which has been experienced at the same time throughout the Presidency and beyond, under varying monsoon conditions, suggest an exaltation in the virulence of the parasite common to all districts on this side of India.

The following tables shows the summary of work done in the year 1924 in connection with malaria prevention:—

Number of wells filled in	102
" " " hermetically covered	17
" " " covered with trap doors	23
" " " inspections of buildings	90,199
" " " notices issued for wells	453
" " " " " cisterns, etc.	1,373
" " " " " cisterns made mosquito-proof	2,779
" " " " " provided with standard covers	2,054
Number of children examined for enlargement of the spleen	10,678
Number of blood slides (random sampling) examined	2,098
Number of blood slides of dispensary patients	689
" " " quinine pills distributed (2 grs.)	9,850
" " " " " " " " " " (4 grs.)	8,200
" " " " " " " " " " (5 grs.)	700
" " " Cinchona febrifuge tablets distributed	32,274
Number of pools treated with pesterine or kerosine emulsion	2,433
Number of old receptacles removed	9,697
" " low-lying areas filled in	40
" " big tanks filled in	2
" " correspondence papers (new cases) dealt with	3,797

Milk Supply.—A considerable advance has been made by the Dairy Superintendent during the year towards the solution of the problem of removing from the city the milch-cattle stables which are so fertile a source of nuisance and complaint.

Land is to be purchased and stables erected by the Municipality at Trombay for the reception of milch-cattle from the city.

In addition to the Trombay scheme for bringing milk in from the suburbs, negotiations have been set on foot with a view to encouraging the production of milk by private enterprise at much greater distances from Bombay in the country where the conditions fulfil the requirements of economic dairy farming.

A total quantity of 23,000 gallons per day is consumed; this is equivalent to 3.1 ounces per head of the population, an amount which must be regarded as insufficient for the consumers, of whom a majority are vegetarians.

In the non-vegetarian diet of a healthy adult efficient substitutes for milk can no doubt be provided, but for

children up to the age of 12 or 14 years and for vegetarians milk may be regarded as essential.

The combined needs of the total population may be stated as amounting to not less than an average of 5 ounces of milk per head per day, which is the average in London. In New York the average exceeds 11 ounces.

Of the milk consumed 78 per cent. is produced in milch-cattle stables within the city, and 1 per cent. is brought in from the suburbs by road. Twenty-one per cent. comes by rail.

During the year 2,130 hawkers importing milk by train were inspected. Nine hundred and twelve were found to have no licence and 713 were carrying the milk in open cans without covers.

Prosecutions were instituted in 346 cases of hawkers found selling milk in the streets without a licence.

Water-supply.—The quantity of water available throughout the year has been well above the average, but the supply is intermittent and the pressure insufficient in many cases to fill the storage cisterns on the roofs of high buildings. Serious nuisance thus arises through the failure of the supply for flushing tanks of water-closets.

No relief will be obtained until the third pipe line from Tansa Lake has been completed. The construction of this pipe line is progressing rapidly.

The filter for the water from Pawai Lake has been completed and progress is being made with the construction of filters for the Vehar and Tulsi Lake supplies. During the rains the water from Tansa Lake was treated with chlorine gas from cylinders passed through the chloronome now installed at Ghatkopar some 5 miles beyond the city limits.

During the year the water-supply from all sources was unfiltered.

Correspondence.

A USEFUL DIGITALIS TINCTURE.

To the Editor, INDIAN MEDICAL GAZETTE.

SIR,—In my article "Clinical Studies on Digitalis in Bengal," which appeared in the *Indian Medical Gazette* of April 1924, it was stated as a result of therapeutic tests on a large series of cases of heart failure in Calcutta that there is no tincture of digitalis that acts in the dose of 5 to 8 drms. as in Europe and America. On the other hand, it was essential and imperative to use massive doses of 2 drms. every day for 8 or 10 days before any conspicuous benefit was obtained.

Several months before this article appeared, the writer was in communication with Messrs. Parke Davis & Co., as a result of which several samples of a new and extremely potent tincture were generously placed at the disposal of the writer. Carefully controlled clinical trials were given on a fairly large number of cases of heart failure, with or without auricular fibrillation. The results were uniformly good and most of the cases developed minor toxic digitalis effects directly a total dose of 5 drms. in 5 days was reached.

Later on, some samples of this new tincture were biologically assayed and the results as worked out by Major R. N. Chopra and Captain P. De and the writer revealed that the same potency was found on cats; in fact, 1 cat-unit was contained in less than 1 c.c. of this tincture.

Therefore making allowance for the effects of climate and the delay in the drug being administered in India, there still remains adequate potency to yield results with the same doses as worked out in Europe and America.

It is therefore an encouraging sign that the above potent tincture has now been placed within the reach of every practitioner in India; the chemists must be congratulated on taking up this matter so promptly. This tincture is called Digifortis.

One word of advice is not superfluous; in Calcutta it is essential to stick to a daily dose of 1 drm. a day in order that the best results may be obtained without much delay. It is of course common knowledge that most of our heart failure cases in Bengal seek medical relief when about to cross the Rubicon, and it is therefore imperative to use adequate doses and get quick results before it is too late.—Yours, etc.,

S. C. BOSE, M.B., M.R.C.P., D.T.M. (Lond.).

86, SOUTH HILL PARK,
HAMPSTEAD,
LONDON, N.W.3.
3rd September 1925.

TINCTURE OF IODINE IN DYSENTERY AND DIARRHŒA.

To the Editor, INDIAN MEDICAL GAZETTE.

SIR,—I have tried tincture of iodine in dysentery and diarrhœa in more than 100 cases and found that excepting a few cases all of them were cured by tincture of iodine administered in ten drops doses three times a day. In order to avoid burning in the throat due to tincture of iodine, I used to add a drachm of glycerin per dose.

I had noted that though some bad cases did not show improvement in 24 hours, still they decidedly showed marked improvement in 48 hours.

I also tried tincture of iodine in malaria and acute gonorrhœa but I was disappointed with the results in these cases though some cases of malaria did improve.

I have found that about 4 injections of the following solution are very useful in curing gonorrhœal epididymitis without any external application or internal medicine.

Iodum	gr. 6
Potas. Iodide.	gr. 6
Aqua Distillata	oz. 1

About 40 minims of the above solution is injected every time on alternate days.—Yours, etc.,

P. N. SHAH, M.B., B.S.,
Medical Officer, Baroda.

MEDICAL STORES,
BARODA,
7th September 1925.

A CASE OF MALIGNANT PUSTULE.

To the Editor, INDIAN MEDICAL GAZETTE.

SIR,—I have read with interest the case described in page 428 of September issue of your journal regarding the incidence of malignant pustule. I had a case which I describe as follows:—

A Muhammadan male, aged 30 years, was admitted to Dumka Sadar Hospital on 18th July 1925. The clinical signs of his ulcer were—right side of face inflamed and swollen distinctly; under the lower eyelid and on the upper part of the cheek was an ulcer $2\frac{1}{2}$ in \times 1 in.; in its centre was a black slough $1\frac{1}{2}$ in \times $\frac{1}{2}$ in. quite fixed to its base; I tried to remove the slough by forceps but I did not pull for fear of unnecessary bleeding; the man had it for one week and had little fever at the beginning; he came to the hospital walking and was not at all ill.

Treatment given—hot fomentations to the ulcer twice or thrice a day; after 4 days the inflammation of the face was much less and he could easily open his right eye. The ulcer was reddish and the slough was decreasing in size. After seven days more he went home to attend a religious festival. He came for the cure of his ulcer after the festival and four days after his re-admission he was cured.

Under microscope—a piece of sloughy tissue when stained showed distinctly anthrax bacilli.

Peculiarities—he had very little toxic symptoms and was not connected with hide business but is an ordinary cultivator of land.

Capt. Pereira, Civil Surgeon, took special care of this man and stained the smears finding the *Bacillus anthracis*.—Yours, etc.,

R. K. BASU,

Medical Officer, Dumka Sadar Hospital.

DUMKA SADAR HOSPITAL,
DUMKA, the 19th September 1925.

OBITUARY.

Brigade Surgeon Lt.-Colonel Wellington Gray, I.M.S.

We regret to announce the death of Brigade Surgeon Lieutenant-Colonel Wellington Gray, I.M.S., which occurred at the age of 83 at 22, Glyn Mansions, West Kensington, London, on July the 15th, 1925. After obtaining his L.M. and L.Ch. degrees from Dublin he passed into the Indian Medical Service on May the 31st, 1866 and arrived on the shores of India on November, the 9th of the same year and took up the duties of Professor of Anatomy and Curator of the Museum in the Grant Medical College, and Second Surgeon to the Sir Jamsetjee Jejeebhoy Hospital, Bombay. He showed infinite patience, care, diligence and industry and gave ample proof of his great surgical skill and aptitude in the art of teaching anatomy while holding this chair from 1866 to 1871.

Colonel Gray made the students realise that the study of anatomy was not merely an accomplishment for the Inter. M.B., B.S., but an essential requisite for the art of surgery. His love of anatomy is immortalised by the "Wellington Gray Medal" which is awarded every year to the best anatomist of the Grant Medical College after a special competitive examination.

Botany was however his one great hobby; he acted as Professor of Botany from 1871 to 1883.

To him is due the credit of laying out so beautifully the grounds of the above mentioned College and Hospital. He was Professor of Surgery and Senior Surgeon from 1882 to 1893 and Principal of the Grant Medical College from 1889 to 1893. He was also Senior Medical Officer to the Sir J. J. Hospital. He was a man of great erudition, untiring energy, and had a keen sense of the dignity of the medical profession which he always upheld.

In Bombay his numerous pupils have the highest respect and regard for him as one of the greatest teachers that have adorned the staff of this institution. A man of extraordinary endowments, he had a brilliant career in the service, and when, in 1893, Colonel Gray retired and left India, after a devoted service of 26 long years in an unbroken connection with the Grant Medical College and J. J. Hospital, the College and the Bombay medical profession felt the loss very keenly. He had a very sympathetic personality which attracted around him a vast number of devoted friends both in the college and outside. He was one of the noblest officers of the Indian Medical Service and will always be remembered as a worthy member of that noble hierarchy of devoted and brilliant medical men (such as Moorehead, Vandyke Carter and others) who have guided the destinies of the Grant Medical College in the past.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Lieutenant-Colonel H. W. Pierpoint, F.R.C.S. I.M.S., is appointed as Superintendent, X-Ray Institute, Dehra Dun, with effect from the afternoon of the 5th October 1925.

The services of Major J. L. Sen, M.C., I.M.S., on relief by Lieutenant-Colonel Pierpoint, are replaced at the disposal of the Government of Assam.

Major J. B. Lapsley, M.C., I.M.S., is appointed Officer-in-charge, Medical Store Depôt, Madras, with effect from the 4th November 1925.

Major R. F. D. MacGregor, I.M.S., an Officiating Agency Surgeon, on return from leave, is posted as Agency Surgeon in Bhopal, with effect from the 16th September 1925.

Major G. Covell, M.D., I.M.S., is appointed temporarily to the Medical Research Department and posted as a supernumerary officer at the Central Research Institute, Kasauli, with effect from the 2nd October 1925.

Major R. W. G. Hingston, M.C., I.M.S., is appointed Surgeon Naturalist, Marine Survey of India, with effect from the 25th September 1925.

The services of Major F. J. Anderson, M.C., M.B., F.R.C.S., I.M.S., are placed permanently at the disposal of the Government of Madras, with effect from the 27th February 1925.

The services of Major A. G. Tresidder, M.D., I.M.S., are placed temporarily at the disposal of the Government of Bombay, with effect from the 1st April 1925.

In modification of previous orders, the services of Captain P. Verdon, I.M.S., are placed permanently at the disposal of the Government of Madras, with effect from the 26th November 1924.

The services of Captain A. M. Ghosh, M.B., I.M.S., are placed temporarily at the disposal of the Government of Bihar and Orissa, with effect from the date on which he assumes charge of his civil duties.

Captain R. Hay, I.M.S., an Offg. Agency Surgeon and Agency Surgeon in Bundelkhand, on return from leave, resumed charge of his appointment, with effect from the 29th September 1925.

Major (now Lieutenant-Colonel) J. D. Graham, C.I.E., M.B., I.M.S., to be acting Lieutenant-Colonel from 3rd March to 28th April 1916, and from 24th December 1916 to 27th December 1919, whilst employed as Assistant Director of Medical Services in Mesopotamia.

RESIGNATIONS.

Captain Manohar Lal Bhagat. Dated 1st September 1925.

Captain Keshav Ganesh Mohile, M.C. Dated 1st September 1925.

RETIREMENTS.

The King has approved the retirement of Colonel E. L. Blenkinsop, M.B., I.M.S., from service with effect from the 4th September 1925.

The King has approved the retirement from the service of Lieutenant-Colonel F. O. N. Mell, C.I.E., M.D., I.M.S., with effect from the 29th August 1925.

NOTES.

PETROLAGAR.

THIS is a perfectly stable homogenous and highly palatable emulsion of the purest mineral oil and prepared agar-agar.

It combines the well-known lubricating properties of mineral oil with the increased volume of the intestinal content associated with the administration of agar-agar. It marks a real advance in the treatment of constipation since the Petrolagar emulsion has properties which distinguish it from plain mineral oil on the one hand and agar-agar on the other.

The oil in Petrolagar is so finely subdivided that it mixes perfectly with the faecal content. This ensures a soft plastic mass which passes evenly through the bowel. The agar-agar is also very finely divided. It has a greater absorption capacity than that of ordinary shredded or powdered agar and increases the volume of the intestinal matter.

Petrolagar is non-habit forming. It is highly palatable and is readily taken by those to whom oil in any other form is objectionable. Whilst thoroughly lubricating the bowel, all danger of oil leakage from the rectum is eliminated.

Petrolagar is a distinct advance in the treatment of *chronic constipation, intestinal stasis and mucous colitis.*

In the treatment of the *intestinal atony* which lies at the root of chronic constipation, it has given, as a large volume of clinical evidence proves, results unobtainable by any other method of medication.

In inflammatory conditions of the large bowel, Petrolagar exerts a soothing protective action which allays pain and irritation. It is also anti-fermentative and very helpful in intestinal flatulence and distension.

In haemorrhoids Petrolagar effects an easy evacuation, so that there is no straining. It supersedes saline purges and those aperients which owe their effect to irritation.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints gratis, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "The Indian Medical Gazette," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to the *Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of the *Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.
